Specialist Review

Protein arrays

Derek Murphy and Dolores J. Cahill
Centre for Human Proteomics, Royal College of Surgeons in Ireland, Dublin, Ireland

1. Introduction

High-density DNA microarray technology has played a key role in the analysis of whole genomes and their gene expression patterns. The ability to study many thousands of individual genes, using oligonucleotide or cDNA arrays, is now very widespread, with its uses ranging from the profiling of gene expression patterns in whole organisms or tissues to the comparison of healthy and pathological samples. This technology together with the sequencing of the human genome has produced vast amounts of gene expression profiling data and, importantly, new bioinformatics tools to handle these data. Such data reveal important information regarding gene expression, however, the function of most genes lies at the protein level. Whether studying, for example, development in a particular organism or disease processes, knowledge of alternations in protein levels, protein structures (including modifications), protein–protein interactions, and so on, is crucial to elucidate with such complex biological phenomena. However, such knowledge is more difficult to attain, even if only one protein is being studied, due to the enormous complexity of the protein world. Alternative splicing, proteolytic events, and posttranslational modifications (e.g., glycosylation, acetylation, phosphorylation) are just some of the events that can occur to gene products, resulting in many more proteins than the genes coding for them. Further, proteins can form complexes with other proteins, cofactors, DNA/RNA, and so on.

Traditional methods for the analysis of proteomes include two-dimensional gel electrophoresis or chromatography, which, when combined with mass spectrometry, enables large-scale separation and identification of proteins, including many of their modifications (Melton, 2004). To complement the functional analysis of proteins on a large scale, proteins can be studied in array formats. Theoretically, such an array would contain functionally active proteins, in all their modified states, immobilized on a surface at high density or in solution in nanowells. However, protein activity is dependent on a wide range of factors (posttranslational modifications, cellular localization, pH, presence/absence of cofactors, etc.), which makes the production of a protein chip containing the whole proteome a daunting task. Current protein and antibody arrays represent the first steps toward this goal.

2. Generation of content for protein arrays

The first requirement toward the generation of protein arrays is a source of large numbers of recombinant proteins. A number of strategies are currently employed to provide sources of thousands of proteins for the generation of protein arrays. One approach is high-throughput cloning or amplification using PCR of defined open reading frames coding for the proteins of interest (Kersten *et al*., 2003; Reboul *et al*., 2003). The successful implementation of such an approach relies on the availability of sequence data and its correct annotation in the databases. In particular, the definition of the open reading frames of alternative splice variants of one protein remains difficult with such an approach. Also, previously uncharacterized proteins will be absent, limiting this approach as a discovery tool. For these reasons, this approach has proved most valuable in the production of chips containing proteins from well-characterized organisms, such as *Saccharomyces cerevisiae* and *Caenorhabditis elegans* (Schweitzer *et al*., 2003).

Another approach is the use of protein expression libraries, which are used for a "shotgun" approach to the generation of recombinant proteins (Bussow *et al*., 1998). Such libraries are generated using mRNA isolated directly from the cell (Lueking *et al*., 2000; Bussow *et al*., 2000). In this approach, mRNA is isolated from the tissue or organism of interest and directionally subcloned into a protein expression vector suitable for heterologous expression in either a bacterial (e.g., *Escherichia coli*) or eukaryotic organism (e.g., yeast) – some solutions exist for the rapid movement of coding region from one organism to another, such as the GATEWAY system (Life Technologies) (Walhout *et al*., 2000) or dual expression vectors (Lueking *et al*., 2000). Not only does this approach circumvent the cloning of individual open reading frames, readily permitting the expression of tens of thousands of proteins, but also this strategy automatically includes splice variants and previously uncharacterized gene products, that is, there is no selection based on presently available databases and annotations.

Both strategies generally use a system by which the expression of the recombinant proteins is controlled by an inducible promoter. Thus, the time and duration of protein expression can be tightly regulated. One common and well-characterized system for expression in bacteria is the IPTG-inducible LacZ promoter. Because recombinant proteins are being expressed in a foreign environment, for example, human proteins expressed in *E. coli*, measures can be taken to improve expression levels. For example, plasmids coding for tRNAs, which are responsible for the translation of codons rarely found in bacteria but more commonly in mammals, can be introduced into the system, for example, the *argU* gene on the pSE111 vector that codes for a rare arginine tRNA (Bussow *et al*., 1998; Brinkmann *et al*., 1989). Other issues can also be addressed such as the expression of proteins that are toxic to the host organism. This remains a challenge; however, a number of systems have been developed to minimize basal level expression of the toxic recombinant protein in the host before induction. One such system for expression in *E. coli* is the pLysS vector (Stratagene), which is a low-copy-number plasmid that carries an expression cassette from which the T7 lysozyme gene is expressed at low levels. This T7 lysozyme binds to T7 RNA polymerase and inhibits transcription by this

enzyme. This approach has been used successfully for high-throughput expression of mammalian proteins in bacteria (Ding *et al*., 2002).

Apart from just the question of expressing the recombinant proteins of choice in a particular host system, there is also the question of tagging these proteins. A large number of tags exist, the coding region of which can readily be introduced into vectors. Depending on the approach taken, many options are available, including N-terminal and/or C-terminal tagging, multiple different tags are also an option, in particular, in conjunction with proteolytic sites for subsequent removal of the tag, if required. These tags can vary in size from the short His_6 tag to the 30-kDa GFP tag. Such tags are required for the detection of the expressed recombinant proteins and, in conjunction with an appropriate affinity separation method, for their purification (more steps of purification can be introduced using multiple tags). For a review of different expression systems, see Braun and LaBaer (2003).

In one example, a human fetal brain cDNA library was subcloned into a bacterial expression vector, permitting controlled IPTG-inducible expression of His6-tagged recombinant proteins. The *E. coli* clones of this library were then arrayed in high density onto PVDF membranes, grown overnight, and recombinant protein expression induced for a controlled length of time. Those clones expressing a human protein are readily detected by means of an anti-His_6 antibody. In this fashion, a protein array containing 10–12 000 different human proteins has been generated (Bussow *et al*., 1998). Approximately 66% of the proteins expressed in this library are, according to present annotation, full length. Also, such proteins have been shown to be readily expressed and purified in high throughput using available automated platforms (Braun *et al*., 2002; Lueking *et al*., 2003). It is such approaches that today allow the generation of protein microarrays.

3. Protein microarrays: toward the proteome on a chip

Once a source of proteins has been established, consideration must be given to the format that a protein microarray can have. For example, there are presently a number of possible surfaces available for the manufacture of such chips. In general, the available surfaces can be divided into two major categories: flat (planar) and 3D (mostly gel-like) surfaces (Angenendt *et al*., 2002; Angenendt *et al*., 2003). Planar surfaces have been primarily developed in the area of cDNA arrays. In general, the glass surface of these chips are treated to produce a thin layer of a particular chemical group, for example, an aldehyde group or poly-L-Lysine (Haab *et al*., 2001). The proteins are bound to the surface of these chips by either covalent bonds or simple electrical charge. Another type of planar chip surface available is plastic polymer-coated slides, such as the MaxiSorb slides from Nunc – an approach used in ELISAs for many years. The simple adoption of technology from the area of cDNA arrays brings with it a number of major concerns when used with proteins. First, unlike DNA, the surface charge of proteins is highly variable and the use of simple uniform electrostatic interaction for the immobilization of different proteins results in large variation in the amount of protein bound. Second, the structural conformation of proteins deposited onto a planar surface cannot be expected to very closely mimic "native" proteins, but would be more similar to

proteins present on membranes, such as in traditional Western blotting or dot blot experiments. Third, there is no control over the orientation of the proteins on the surface, which may result in, for example, the inaccessibility of an active site.

The development of the gel-like 3D chip surface was partly driven in an attempt to minimize the denaturation of the immobilized proteins in the arrays. A number of such surfaces exist based around polyacrylamide and agarose coated on a glass surface, which provide a hydrophilic environment for the proteins. Such surfaces allow the user to adjust various conditions, such as pH and salt concentrations, by incubating the chips in the appropriate buffer. Using a "homemade" polyacrylamide surface, a glass chip containing 2413 nonredundant purified human fusion proteins, arrayed at a density of up to 1600 proteins cm^{-2}, has been successfully employed in antibody binding studies, including the screening of human sera samples (Lueking *et al*., 2003), indicating the maintenance of a degree of structural conformation of the proteins involved. There are also non-gel-like 3D surfaces available, such as the FAST slides from Schleicher and Schuell, which have a nitrocellulose surface. Like any 3D surface, this surface will allow a much higher concentration of proteins per spot. One advantage of the nongel 3D surface is the increased shelf life of these slides.

However, these surface solutions still leave the problem of controlling the orientation of the proteins on the surface of the slides, which is necessary to maximize the activity of these proteins. For example, in order to maximize the binding of antibodies arranged on a surface to their epitopes, it would clearly be an advantage if the heavy chain were attached to, or close to, the surface and the antigen-binding site as far away from the surface as possible. One approach has been the use of affinity tags, for example, a nickel-coated slide has a natural and specific affinity to His_6-tagged recombinant proteins. This approach was used to array 5800 yeast proteins that were screened for their ability to interact with calmodulins and phospholipids (Zhu *et al*., 2001). Similarly, successful orientation of antibodies and antibody Fab fragments was achieved by biotinylating such antibodies/Fab fragments and arraying them on a streptavidin-coated surface (Peluso *et al*., 2003). A further development of surface chemistry involves the use of a polyethylene glycol layer (PEG) (Angenendt *et al*., 2003) or dendrimers (Benters *et al*., 2002; Benters *et al*., 2001). These approaches involve the coupling of the proteins to epoxy groups, which act as spacers preventing direct protein-surface contact and, thus, eliminate the need for blocking reagents to reduce background binding. One further development of this approach has been to link chelating iminodiacetic acid groups to PEG, which in turn can be bound by Cu^{2+} ions and so provide a highly specific binding site for His_6-tagged proteins (Cha *et al*., 2004). The authors demonstrated one additional, and potentially very important, use for such technology and that is the elimination of the need for prepurification of tagged recombinant proteins for arrays. A number of studies have been carried out comparing the different surfaces available for protein array work, including antibody arrays that assess background noise, sensitivity/detection limits, reproducibility, and storage for a variety of experimental designs (Angenendt *et al*., 2002; Angenendt *et al*., 2003).

4. Microfluidic chips

While the development of 3D surfaces and spacers goes some way to address the problems faced when looking at protein–protein interactions on a chip, many experiments that involve interactions of proteins in a functional state will prove difficult to perform on these chips, which is obviously a major drawback of the current protein arrays. Ideally, we would like to look at protein interactions, where the proteins are in their native state and are functional, that is, in conditions as close as possible to those in nature. This may be solved by developing a microfluidic chip, which is a series of enclosed microchannels within a chip format, such as silicon, plastic, or glass. The potential of microfluidic chips would include the ability to maintain proteins in their functional conformations and to therefore perform interactions such as protein–protein, protein–peptide, protein–compound, protein–DNA, protein–ligand, and protein–antibody interactions in solution. Also, the area of enzyme studies would greatly profit from such a system. In fact, the first steps have been taken to use a "lab-on-a-chip" to study some of the reactions in the glycolytic pathway of yeast (Young *et al*., 2003). Using this system, enzymatic reactions in volumes as low as 6.3–8 nL could be studied (Dietrich *et al*., 2004). The ability to use such small volumes in microfluidic chips is very important due to the high cost of proteins, antibodies, compound libraries, peptides, and even the difficulties in obtaining enough patient samples to screen in this format, when screening in high throughput, can be prohibitive. Such technology would also allow us to fully exploit the libraries of proteins that currently exist.

Recent developments show that microchannels can be generated in plastic, where the microchannels have a diameter of $100\,\mu\text{m} \times 100\,\mu\text{m}$, can be centimeters in length, and can be fabricated using glass, silicon, and plastic (Guber *et al*., 2004). However, there are current technological challenges, which need to be addressed, such as loading, sample positioning and manipulation of samples in these chips, handling nanoliter volumes, and scanning the chip.

5. Applications of protein arrays

Theoretically, present protein arrays provide a tool to examine interactions with proteins, whether they be with other proteins (including antibodies), peptides, DNA/RNA, or chemical compounds on a large scale. In one proof-of-principle experiment, a small number of well-defined protein–protein interactions, including an interaction dependent on a small molecule, were demonstrated in a microarray format (MacBeath and Schreiber, 2000). While still somewhat in its infancy, a number of studies have been completed in which high-throughput screening of protein microarrays has proven successful. As mentioned above, calmodulin- and phospholipids-interacting proteins have been identified by screening almost 6000 yeast proteins, generated by expressing previously annotated open reading frames (Zhu *et al*., 2001). A human protein expression library, involving in situ expression of tens of thousands of recombinant proteins on large membranes (Bussow *et al*., 1998; Lueking *et al*., 1999), has been successfully screened to demonstrate antibody–protein interactions. This same library has also provided a

source of purified recombinant proteins for microarrays, which were demonstrated to be a successful platform for the large-scale study of protein–antibody interactions (Lueking *et al*., 2003), an important step toward large-scale studies of antibody specificity. By screening thousands of different proteins from the relevant organism with a particular antibody, it is possible to determine which proteins contain antigens recognized by the antibody in question. In another study (Michaud *et al*., 2003), 11 polyclonal and monoclonal antibodies were screened against 5000 yeast proteins and the results demonstrated the cross-reactivities of many of the antibodies screened.

One further development of the study of protein–antibody interactions is using high-content protein arrays to determine the target of antibodies previously identified as potentially interesting markers in disease. Our group is presently working to identify the antigens of antibodies, initially identified by immunohistochemistry as interesting markers in certain types of cancer (Figure 1 shows a pipeline for this work). Each antibody can be screened against an appropriate protein expression library, arrayed on either PVDF membranes or, as purified proteins, arrayed on glass chips. Unlike previous approaches, which could at best identify potential epitopes of a particular antibody, this approach identifies the actual target protein. In addition, potential cross-reacting proteins can also be identified using this method, which is important information for assessing an antibody in disease-screening procedures. Similarly, protein arrays could provide a useful screening technique to be introduced into any antibody production process. For example, during the production of monoclonal antibodies in mice immunized with a particular antigen,

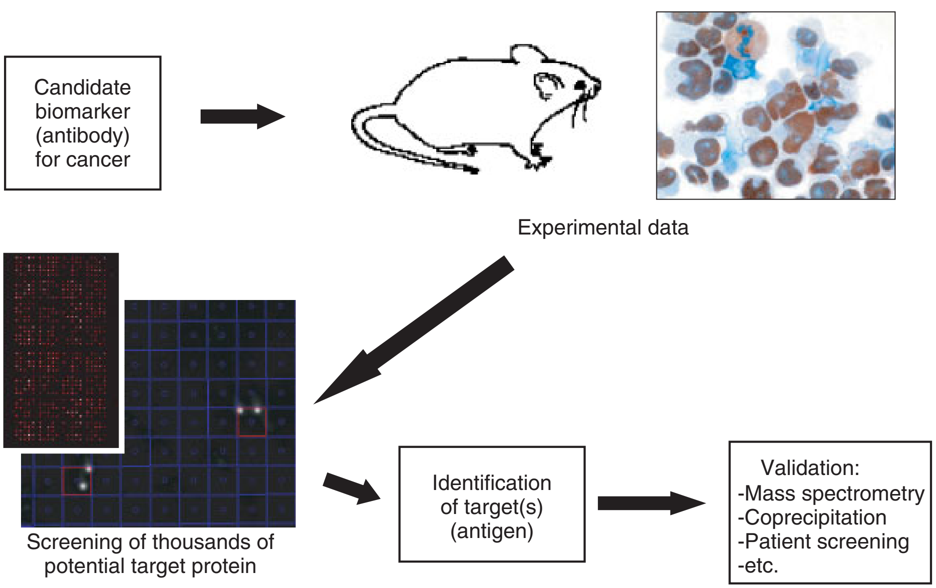

Figure 1 Pipeline showing integration of protein array technology into cancer marker discovery and characterization. Antibodies that are potentially useful as cancer markers are produced and tested, for example, using immunohistochemistry. Protein array technology can then be introduced to confirm/discover the protein target bound by the antibody, and assess the specificity/cross-reactivity

the antibody-producing B cells are fused with myeloma cells to form hybridomas, which can then be cultured for large-scale expression of the antibody. During this process, the supernatant from each hybridoma clone is screened for the ability of the antibody present to bind to the target antigen. By introducing a screen of a large-content protein array at this point, the antibody could be tested not only for its ability to bind the known antigen, but valuable data on specificity/cross-reactivity could also be generated.

Just as it is possible to characterize the binding of a single antibody using protein arrays, it is also possible to characterize many antibodies present in a single sample, such as to profile the antibody repertoire in serum or plasma. One immediate application is the use of "allergen arrays" to screen for the presence of particular IgE molecules in a patient sample. The traditional approach involves the use of simple extracts from potential allergens. Such extracts, containing both allergens and nonallergens, are commonly used in skin prick tests to determine the possible source of an allergic reaction in the patient. Using modern arraying technology and recombinant allergens (e.g., pollen and fungus proteins) relatively large arrays have been produced for screening purposes (Hiller *et al*., 2002; Deinhofer *et al*., 2004; Jahn-Schmid *et al*., 2003; Wiltshire *et al*., 2000). These arrays can also readily include nonprotein allergens such as latex, and so on. Such arrays are readily miniaturized, permitting the screening of very low volumes of a patient's blood, and are also more accurate in identifying the precise source of the allergic response.

In a similar fashion, protein arrays can be used to profile antibodies present in the blood of patients with autoimmune diseases. Initial autoantigen arrays consisted of almost 200 proteins, peptides, and other biomolecules (including several forms of dsDNA and ssDNA), which were known autoantigens to several well-characterized autoimmune diseases, including rheumatoid arthritis and systemic lupus erythematosus (Robinson *et al*., 2002). Another approach is to use large arrayed libraries of recombinant proteins as a potential autoantigen array. In a proof-of-principle experiment, a protein array chip containing almost 2500 purified recombinant human proteins was used to profile the autoantibodies present in small volume samples from patients with alopecia and rheumatoid arthritis (Lueking *et al*., 2003). This approach permitted the identification of previously known autoantigens and also previously uncharacterized protein autoantigens. Initial results from screening a large recombinant mouse protein array also indicate the usefulness of this approach to characterize autoimmune disease in a mouse model system for systemic lupus erythematosus (C. Gutjahr, 2005). Protein arrays can contribute enormously to our understanding of the general mechanisms involved in autoimmunity, as well as provide a platform on which to develop the technology for more complete diagnostics of the various autoimmune diseases.

Presently, the use of protein array screening to identify protein–protein (nonantibody) interactions is still very much in its infancy and limited to specialized laboratories. Many proteins are difficult to study in solution (e.g., membrane proteins) or may require the presence of various cofactors. Another approach to screening "difficult" proteins is the use of peptide screening.

Figure 2 shows an outline of the approach taken by our group to identify proteins that interact with the cytoplasmic tail of a membrane protein, in this

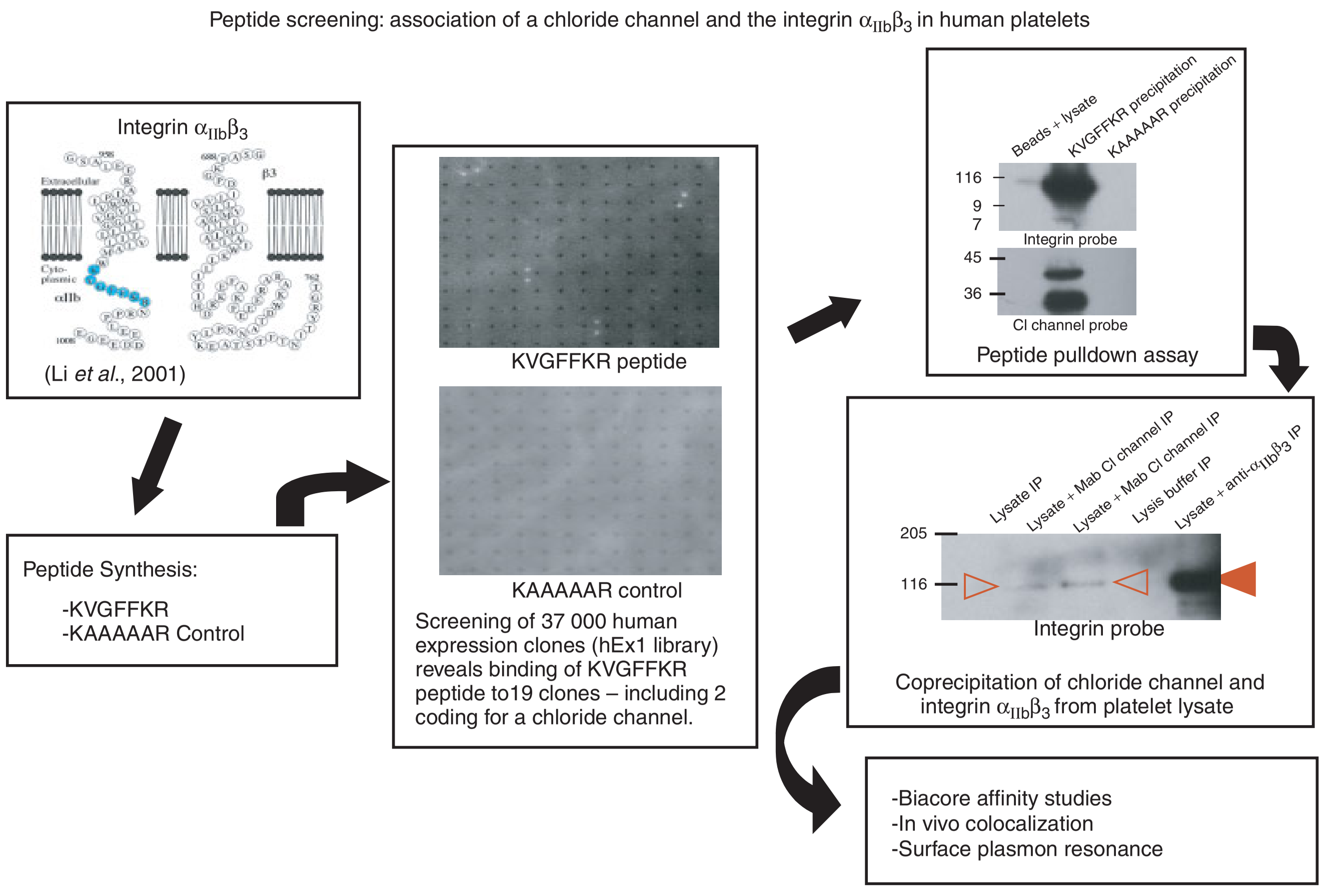

Figure 2 Example of the identification of protein–protein interactions using protein arrays. In order to identify proteins that potentially interact with the cytoplasmic tail of the platelet integrin $\alpha_{IIb}\beta_3$, a labeled peptide of this region was generated and a protein array library with over 37 000 clones was screened. One of the proteins identified, the chloride channel ICln, was further characterized and confirmed as an interaction partner of the integrin in biological systems (Larkin *et al*., 2004) (Reproduced by permission of American Society for Biochemistry & Molecular Biology)

case a platelet integrin (Larkin *et al*., 2004). The particular conserved α-integrin cytoplasmic motif, KVGFFKR, had previously been shown to play a critical role in the regulation of activation of the platelet integrin $\alpha_{IIb}\beta_3$ (Stephens *et al*., 1998). In order to discover the molecular mechanisms involved in this regulation, it is necessary to discover what proteins are interacting with this integrin, and more specifically with this region of the cytoplasmic tail. In order to overcome the difficulties associated with working with entire membrane proteins, a tagged peptide (biotin-KVGFFKR) was synthesized corresponding to the region of interest. This peptide was then screened against a high-density array of 37 000 *E. coli* clones expressing recombinant human proteins (Bussow *et al*., 1998; Lueking *et al*., 1999), and 19 clones, coding for 13 different proteins, were identified as binding the labeled peptide. Of these 19 clones, a strong binding could be shown between this labeled peptide and purified proteins isolated from three clones. Of these clones, one codes for a protein that could not be shown to be present in platelets, and two code for a putative chloride channel, ICln, shown for the first time to be present in platelets. A number of experiments were carried out, including peptide pulldown assays and coprecipitation experiments, to confirm the interaction between ICln and integrin $\alpha_{IIb}\beta_3$ (see Figure 2 and Larkin *et al*., 2004). Such an experiment reveals the enormous potential of a protein array approach, not only in identifying novel protein interactions but also toward teasing apart biological pathways in general.

Applications of protein array technology such as target identification and characterization, target validation, diagnostic marker identification and validation, preclinical study monitoring, and patient typing seem to be feasible. We have recently reviewed the value of recent combinations of efforts in genomics, proteomics, and biochip technology and their impact on the overall drug development process (Huels *et al*., 2002). For the first time, tools are available to study disturbances within biological systems, such as disease or drug treatment, on the gene and protein expression levels.

Proteins, as targets, dominate pharmaceutical R&D with ligand–receptor interactions and enzymes as the vast majority, comprising ~45% and 28%, respectively, of the targets (Drews, 2000). Additionally, many therapeutic proteins, especially humanized antibodies, are in clinical development. The ultimate tool for high-throughput and significant screening would be to test new leads or new targets in a highly parallel manner. Some examples for applications in this direction already exist. Recently, an immunosensor array has been developed that enables the simultaneous detection of clinical analytes (Rowe *et al*., 1999). Here, capture antibodies and analytes were arrayed on microscope slides using flow chambers in a cross-wise fashion. This current format is low-density (6×6 pattern) but has high-throughput potential, as it involves automated image analysis and microfluidics; it is already becoming one of the future formats for enzyme activity testing and other assays (Cohen *et al*., 1999). In another study, small sets of active enzymes were immobilized in a hydrophilic gel matrix. Enzymatic cleavage of the substrate could be detected and inhibitors blocked the reaction (Arenkov *et al*., 2000). More recently, an enzyme array that is suitable for assays of enzyme inhibition has been reported (Park and Clark, 2002). Initial publications in the area of receptor–ligand interaction studies in a microarray format have shown that the interaction of immobilized compounds and proteins in solutions can be determined (Zhu *et al*.,

2001; MacBeath and Schreiber, 2000; Mangold *et al*., 1999). This technology allows high-throughput screening of ligand–receptor interactions with small sample volumes.

The multiparallel possibilities of protein array applications have the potential to not only allow the optimization of preclinical, toxicological, and clinical studies through better selection and stratification of individuals but also to effect how diagnostics are used in drug development.

2D DIGE

Kathryn S. Lilley
University of Cambridge, Cambridge, UK

1. Introduction

Two-dimensional polyacrylamide gel electrophoresis (2D PAGE) has been widely used over the past four decades to resolve several thousand proteins in a single sample. This has enabled the identification of the major proteins in a tissue or subcellular fraction by mass spectrometric methods. In addition, 2D PAGE has been used to compare relative abundances of proteins in related samples, such as between mutant and wild type organisms or control and diseased tissues, allowing the response of classes of proteins to be determined. To date, the majority of comparative protein-profiling studies have produced qualitative data, which have enabled the investigator to determine whether or not a particular protein shows an increase or decrease in expression. This provides no measure of the extent of this change in expression, therefore, it is unsuitable for the clustered data analysis needed for an insight into functionality. Quantitative proteomics allows coexpression patterns to be studied, and proteins showing similar expression trends may be assigned membership of the same functional groups; however, quantitation has been hampered by several factors. Firstly, silver staining, being more sensitive than Coomassie staining methods, has been widely used for high-sensitivity protein visualization on 2D PAGE, but it is unsuitable for quantitative analysis as it has a limited dynamic range. The most sensitive silver staining methods are also incompatible with protein-identification methods based on mass spectrometry. More recently, the Sypro family of postelectrophoretic fluorescent stains (Molecular Probes, Eugene, Oregon, USA) have emerged as alternatives, offering a better dynamic range than silver staining and ease of use (Malone *et al*., 2001). Another problem is the irreproducibility of 2D gels; no two gels run identically meaning that corresponding spots between two gels have to be matched prior to quantification. Finally, normalization has proved challenging, especially in the case of silver staining where staining is protein dependent. These aforementioned factors all add variability to the system that make it unsuitable for the accurate quantitation.

Difference gel electrophoresis (DIGE) circumvents many of the issues associated with traditional 2D PAGE, such as gel-to-gel variation and limited dynamic range, and allows more accurate and sensitive quantitative proteomics studies. This minireview is an overview of this technique, describing its strengths and limitations.

The DIGE technique was first described some time ago by Jon Minden's laboratory (Ünlü *et al*., 1997) and is now available as a technique from Amersham

Biosciences. This technique relies on preelectrophoretic labeling of samples with one of three spectrally resolvable fluorescent CyDyes (Cy2, Cy3, and Cy5), allowing multiplexing of samples into the same gel. There are currently two types of CyDye labeling chemistries available from Amersham Biosciences.

2. Minimal labeling

The most established chemistry is employed in the "minimal labeling" method, which has been available from this supplier since July 2002. Here, the CyDyes are supplied with an *N*-hydroxy succinimidyl ester group that reacts with the epsilon amino group of lysine side chains. Labeling reactions are engineered such that the stoichiometry of protein to fluor results in only 2–5% of the total number of lysine residues being labeled. It is imperative to keep a low dye:protein ratio to avoid multiple dye additions, as these would result in multiple spots being resolved in the second dimension of the DIGE gel. The typically high lysine content of most proteins makes it challenging to force the labeling reaction to saturation without using excessive amounts of reagent. The fluors carry an intrinsic charge of +1, such that the pI of the protein is preserved upon labeling. The three fluors are also mass matched, each labeling event adding approximately 500 Da to the mass of the protein. Labeling with CyDye DIGE Fluors is very sensitive with a detection limit of around 500 pg of a single protein and a linear response in protein concentration over at least five orders of magnitude. In comparison, the limit of detection with silver stain is in the region of 1ng of protein with a dynamic range of no more than two orders of magnitude (Lilley *et al*., 2002; Tonge *et al*., 2001). The labeling system is compatible with the downstream processing commonly used to identify proteins, which involves the generation of tryptic peptides. Trypsin cleaves the peptide bonds on the C-terminal side of lysine and arginine residues, but, as so few lysine residues are modified by dye labeling, peptide generation is largely unhindered. It is also unlikely that a peptide modified with a CyDye DIGE Fluor would be extracted from a gel piece, hence, interference by the fluors in peptide mass fingerprinting and de novo sequencing mass spectrometric techniques is minimal. A drawback of this minimal labeling system is the fact that the majority of the protein within a sample remains unlabeled and, in the case of smaller molecular weight species, the labeled portion of the protein may migrate to a slightly different position on a 2D gel. To ensure that the maximum amount of protein is excised for downstream processing, minimally labeled DIGE gels are often poststained with a total protein stain such as SyproRuby.

3. Saturation labeling

The second more recent chemistry was released by Amersham Biosciences in July 2003 and is designed for use in situations where sample abundance is limited. This differs from the original *N*-hydroxy succinimidyl chemistry in that CyDyes with no intrinsic charge are supplied with a thiol-reactive maleimide group. These "saturation" dyes are utilized in such a way to bring about labeling of every

cysteine residue within a protein. The saturation labeling is much more sensitive as more fluorophor is introduced into each protein species, Shaw *et al*. reporting an order of magnitude increase in sensitivity over the original minimal dyes (Shaw *et al*., 2003). While the added sensitivity that these dyes provide is desirable, their use is technically more challenging. The reaction conditions have to be carefully optimized for each type of sample to ensure complete reduction of cysteine residues and a protein:dye ratio sufficient for stoichiometric labeling. Substoichiometric labeling will lead to multiple spots in the second dimension, whereas the use of too much dye may lead to unwanted addition reactions with lysine residues, resulting in the formation of charge trains in the first dimension. It is also impossible to compare the 2D spot maps between samples labeled with the two chemistries. Proteins containing multiple cysteine residues may appear as larger molecular weight species when labeled with the saturation dyes. For studies where identification by mass spectrometric techniques is required, a preparative gel with increased protein loading will be required to produce a 2D protein map. In situations where the amount of sample is very small, this technique at best can be considered of diagnostic value. The use of these saturation dyes is not well established, and the maleimide dyes are currently only available for Cy3 and Cy5.

4. Experimental design

DIGE is a particularly powerful approach to study the changes in protein abundance in experimental studies involving comparison of multiple samples. In such studies involving the use of minimal dyes, it is desirable to label samples with either Cy3 or Cy5 minimal dyes, whereas Cy2 is used to label a pooled sample comprising equal amounts of each of the samples within the study, and acts as an internal standard (see Figure 1). This ensures that all proteins present in the samples are represented, allowing both inter- and intra-gel matching. Variation in spot volumes due to gel-specific experimental factors, for example protein loss during sample entry into the immobilized pH gradient strip, will be the same for each sample within a single gel. Consequently, the relative amount of a protein in a gel in one sample compared with another will be unaffected. The spot volumes are normalized for dye discrepancy, arising from differences in laser intensities, fluorescence, and filter transmittance, using a method based on the assumption that the majority of protein spots have not changed in expression level (Alban *et al*., 2003). The spot volumes from the labeled samples are compared to the internal standard giving standardized abundances. This allows the variation in spot running success to be taken into consideration. For the analysis, software developed for the DIGE system (DeCyder™ by Amersham Bioscience, Sweden) is typically used. This software has a codetection algorithm that simultaneously detects labeled protein spots from images that arise from the same gel and increases accuracy in the quantification of standardized abundance (Alban *et al*., 2003). The standardized abundances can then be compared across groups to detect changes in protein expression. In the case of the saturation dyes, where a Cy2 label is not available, the internal standard is labeled with one of the dyes and individual samples appear on separate gels labeled

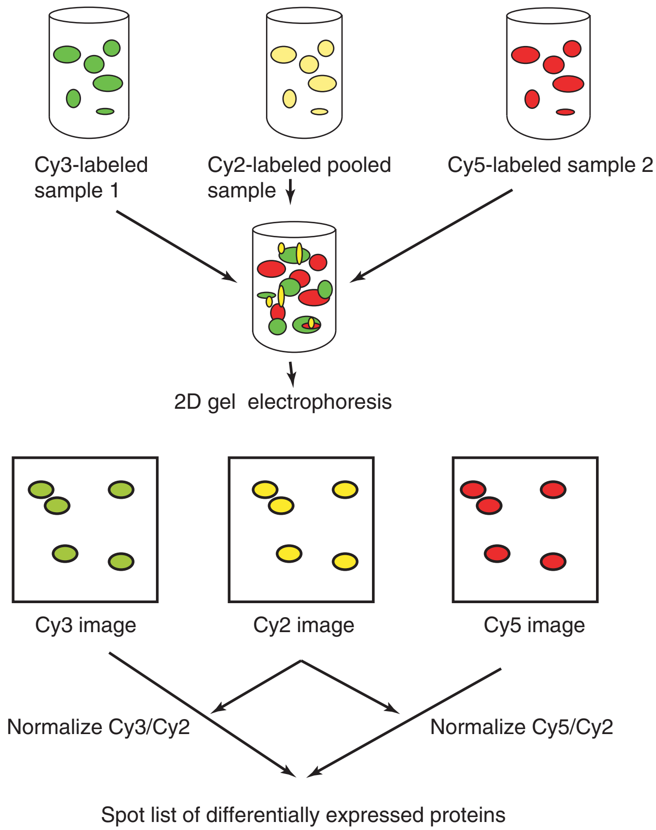

Figure 1 Schematic outline of a 2D DIGE study using an internal pooled standard constructed from equal amounts of all the samples in the study, labeled with Cy2. Samples 1 and 2 are labeled with either Cy3 or Cy5. Each 2D gel performed within the study will have the sample Cy2 standard, combined with the Cy3 and Cy5 labeled samples prior to electrophoresis. The spot intensities from samples 1 and 2 can be normalized using the corresponding Cy2 spot intensities. This approach allows the measurement of more subtle protein expressional differences with increased statistical confidence

with the other dyes. This approach reduces the extent of multiplexing and increases the number of gels within a comparative experiment (Shaw *et al*., 2003).

The design of a protein-profiling analysis experiment using DIGE is crucial to the amount of statistical significance that can be placed on the data. Consideration must be given to methods employed to assess both biological and experimental noise within the system being studied and ample biological and technical replicates must be processed. It is essential to measure the experimental variation in the DIGE process for any new set of samples. This can be achieved by running sets of gels where the same sample is labeled with all dyes to be used, loaded onto one gel, and fully analyzed. This will also give an indication of the inherent error in the system and suggest the threshold of significance or a fold change above which true changes in expression can be measured. In the case of the minimal dyes, a system bias at low spot volumes is observed owing to the different fluorescence characteristics

of acrylamide at the different wavelengths of excitation for each of Cy2, Cy3, and Cy5. This system bias can be greatly reduced by employing a dye swap approach; several replicate gels are run where each sample appears with the opposite labeling, that is, gel 1 would contain pooled sample in Cy2 channel, wild type in Cy3 channel, and mutant in Cy5; gel 2 would contain pooled sample in Cy2 channel, mutant in the Cy3 channel, and wild type in Cy5 channel (Karp *et al*., 2004). The multigel approach allows many data points to be collected for each group to be compared. Spots of interest can be selected by looking for significant change across the groups, for example, with a univariate statistical test, for example, Student's t-test or analysis of variance (ANOVA). These give a probability score (p) for each spot. This score indicates the probability that the groups are the same, consequently a spot with a low score, for example, $p < 0.05$, represents significant difference in relative abundance. The number of replicates required in a study depends on the amount of variation in the system being investigated and on how small the changes in expression are that you wish to measure at a given confidence level. Increasing the number of replicates will increase confidence in smaller changes in expression.

5. Drawbacks of the system

Regardless of the benefits of DIGE, the 2D PAGE process itself has some limitations. For global expression analysis, every protein should be resolved as a discrete detectable spot, The following groups of proteins, however, are often poorly represented: those with extreme isoelectric points (pI) or molecular weight; hydrophobic proteins; lower abundance proteins. It has been calculated that somewhere in the region of 90% of the total protein of a typical cell is made up of only 10% of the 10 000–20 000 possible different species, and hence many low abundance proteins may not be detectable (Zuo *et al*., 2001). Co-migration is also an issue, with proteins of similar pI and denatured molecular weight becoming focused at the same position of the gel. This makes it impossible to accurately determine the relative abundance of an individual protein within a mixed spot. There continues to be improvements to the 2D PAGE technique, however. Enhanced resolution of protein species can be achieved by the use of narrow range immobilized pH gradient (IPG) strips and/or prefractionation of sample; these greatly improve the chance of identification and assignment of function to scarce species (Tonella *et al*., 2001). Membrane proteins remain a problem. The use of more rigorous detergents such as amidosulphobetaine 14 (ASB14) has increased the number of membrane-associated proteins, which can be resolved by 2D PAGE (Santoni *et al*., 2000). In the case of studies involving integral membrane proteins, a 2D PAGE approach should be avoided and differential isotopic labeling strategies involving protein digestion in solution digestion to peptides employed (Li *et al*., 2003).

One of the main criticisms of DIGE is the financial outlay necessary to install the system in a laboratory. An appropriate scanning system and dedicated software are required and the cost of CyDyes necessary for large scale studies is not trivial.

6. Applications of DIGE

To date, the DIGE technology has been used with great success to study a variety of systems, allowing the detection of more subtle changes in protein expression than conventional methods where separate samples are loaded onto each gel (Gade *et al*., 2003); these include breast cancer cells (Gharbi *et al*., 2002), cat brain (Bergh *et al*., 2003), esophageal cancer cells (Zhou *et al*., 2002), yeast (Hu *et al*., 2003), chloroplast (Kubis *et al*., 2003), GPI-anchored proteins (Borner *et al*., 2003), murine mitochondria (Kernec *et al*., 2001), mouse brain (Skynner *et al*., 2002), and rat heart (Sakai *et al*., 2003), although as yet there is a dearth of publications where the internal standard system is used. Knowles *et al*. (2003) have described a significant increase in the accuracy of determination of differential protein expression using the Cy2-labeled internal standard approach. They compared the relative abundances of proteins in cerebral cortex from wild-type mice and neurokinin 1 receptor knockout mice to elucidate molecular pathways involving this protein. They also compared relative abundances and significance values for differentially expressed spots derived from gels incorporating the pooled Cy2-labeled standard with values derived from the same gels, but without normalizing spot volumes to the corresponding pooled standard. They demonstrated that virtually all differentially expressed spots gave lower significance levels and a higher incidence of false–positives when derived without using the pooled standard for normalization. The authors reported being able to measure as little as 10% change in abundance with 95% confidence ($p < 0.05$).

In conclusion, 2D DIGE is the most powerful 2D PAGE-based approach for widespread protein-profiling studies by virtue of the ability to multiplex and link samples across numerous different gels in a study using an internal standard. This approach also gives information about more subtle changes in protein expression than conventional 2D PAGE. The advent of the saturation dyes has increased the sensitivity of this system. The use of 2D DIGE, however, will not result in a global analysis of a proteome as membrane proteins and proteins with extremes of pI and molecular weight will be poorly represented. In this respect, other quantitative techniques such as differential labeling with stable isotope can be considered to be complementary.

Michael J. Dunn
Proteome Research Centre, University College Dublin, Conway Institute for Biomolecular and Biomedical Research, Dublin, Ireland

1. Introduction

Quantitative analysis of 2D gel electrophoresis (*see* Article 29, **Two-dimensional gel electrophoresis (2-DE)**, Volume 5) is faced with a number of challenges. Although at first glance the resolution of 2-DE seems impressive, it is still not sufficient compared to the enormous diversity of cellular proteins. Comigrating proteins in the same spot are not uncommon (Figure 1a). In general, 2-DE has a maximum dynamic range of 10^4. At this value, the scarcest proteins require an expert eye to discriminate valid spots from noise (Figure 1c). In addition, spots tend to have symmetric diffusion in the pI dimension but often severe tails in the M_r dimension (Figure 1b). Another major issue is geometric deformation due to casting, polymerization, and the running procedure, making it difficult to quantify differential expression (Figure 1d). Other issues include contrast variations (Figure 1e) due to stain exposure, sample loading errors and protein losses during processing.

For a biochemist to analyze a single pair of gels for differential protein expression, bearing in mind the thousands of candidate proteins, it requires several hours of expert analysis. There is a great economic argument and substantial efficiency gains to be had in eliminating this bottleneck with the use of large-scale automated processing. In general, the image processing pipeline for 2-DE includes:

- Preprocessing of the gel images
- Spot segmentation, modeling, and expression quantification
- Image registration to correct for geometric and intensity deformation
- Identification of differential expression
- Interpretation, either manually through visualization or with image data mining
- Creation of federated 2-DE databases.

2. Preprocessing

The purpose of preprocessing is the removal of image artifacts to improve the general quality of the images. The techniques used are not significantly different

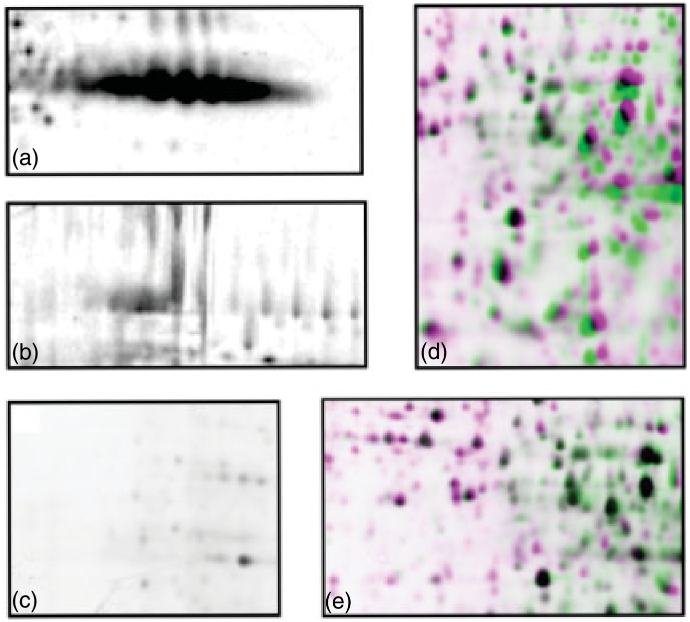

Figure 1 Common problems for computational image analysis as illustrated on silver stained gels: (a) Comigrating spots forming a complex region. (b) Streaking and smearing. (c) Weak spots. Two superimposed gels, one green and one magenta, show (d) nonlinear local distortions between the gels, and after spatial registration, (e) regional intensity inhomogeneities

from other disciplines in digital imaging. For example, in order to correct for uneven background intensity, mathematical morphology is used. The method treats the gel as a topographic relief, where the protein spots are depressions, and variability is estimated by opening the image with a spherical structuring element "the rolling ball", which is larger than the largest spot but with more curvature than the background. To correct for current leakage, which causes a global "frown" in gels whose sides are not fully isolated, model-based processing techniques are used (Gustafsson *et al*., 2002). The parameters are estimated by fitting a straight line to the cathode and a low-degree polynomial to the gel front. The space of gel front curves is searched for the optimal least squares fit.

3. Spot modeling

Traditional methods for differential expression analysis involve explicit modeling of the protein spots. Spot detection concerns the individual resolution of each spot into spot centers, intensities, and geometric properties. Currently, the most popular segmentation technique is the watershed transform (WST). A watershed is the boundary of a region (catchment basin) in a landscape where all water drains to a common point (Figure 2a). The most popular algorithmic approach by Vincent and Soille follows the immersion principle. Imagine piercing all local minima and slowly submerging the landscape in water. Where catchment basins merge

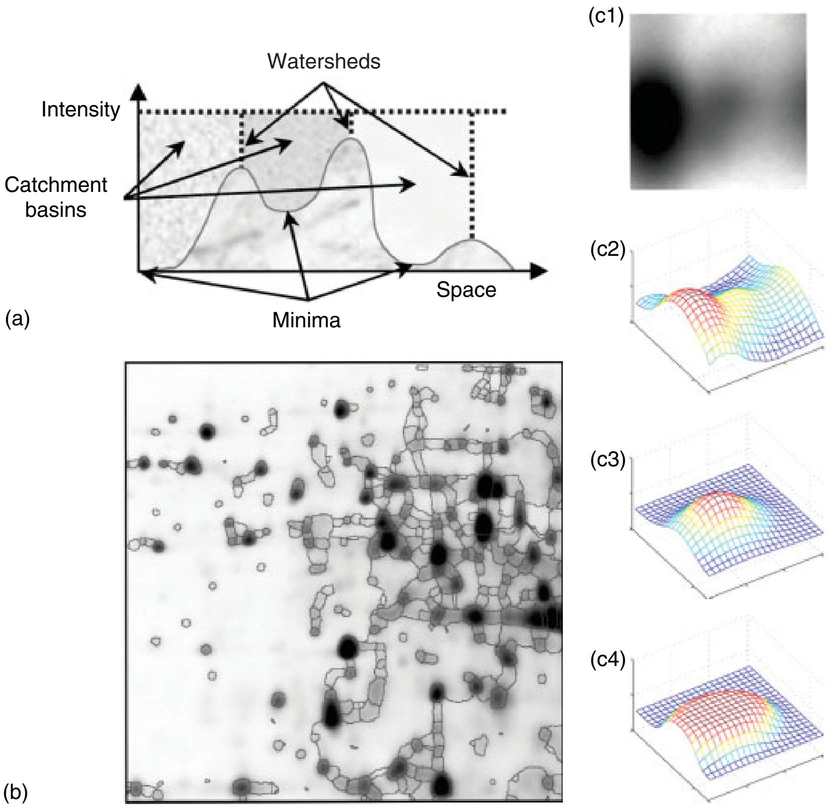

Figure 2 (a) Cross section of a region processed by the watershed transform (WST), treated by the immersion principle of Vincent and Soille. (b) Oversegmentation by the WST. Then the shoulder spot seen in image (c1), with 3D representation (c2), is fitted by both (c3) a 2D Gaussian, and (c4) the diffusion model

dams are built and watershed points are labeled. Noise cause oversegmentation (Figure 2b), which can be minimized through extra restrictions before (marker controlled watersheds) or after (region merging) segmentation.

Spots can overlap in a way that only one segment is found (Figure 2c1, 2c2), so greater prior information of spot shape and its parametric composition is required. Traditionally, this involves optimizing the parameters of a two-dimensional Gaussian (Figure 2c3) to minimize the squared residuals. When saturation effects occur, the spot can no longer be modeled by a Gaussian, and a simplified diffusion process (Bettens *et al*., 1997) is used instead (Figure 2c4). Recently, statistical point distribution models generated from training data have been used (Rogers *et al*., 2003). The principle modes of variation of points placed on the boundary of each spot are captured using PCA. In heavily saturated regions, gradient information cannot be used, and thus a linear programming solution with elliptical elements has been proposed (Efrat *et al*., 2002).

After spot detection, characteristic information about each spot is extracted both to quantify the protein expression and to aid in the spot matching process.

Typical measurements include integrated optical density (VOL: the sum of the pixel intensities), the scaled volume (SV: the volume of a spot normalized with respect to background), and pI/M_r interpolation.

4. Image registration

Image registration represents a class of techniques to align and normalize two images "optimally". Geometric and intensity distortion attributed to experimental uncertainty (i.e., protein diffusion in 2-DE) is undesirable and therefore should be eliminated. On the other hand, intrinsic difference (i.e., changes in protein expression) must be kept. The source image I_s is brought into alignment with the reference image I_r, constrained by the space of allowable transformations (mappings) on I_s, M, and guided by the similarity measure function *sim* – which is at a maximum when the alignment is optimal.

Point pattern matching (PPM) is the standard feature-based approach used today, which finds the closest spot correspondence between a point-pattern (source spot list) and a target point set (reference spot list). Owing to differential expression and inaccuracies in spot detection, these methods need be robust to outliers and allow nonlinear distortions. A wide variety of PPM methods have been developed that include iterative closest point (ICP), the alignment method, bipartite graph matching (geometric hashing), expectation maximization, dynamic programming, and robust pattern matching (RPM). Only RPM methods interleave image warping directly. An issue with feature matching is the number of candidate transforms that need to be evaluated, due to a combinational explosion when each arc (drawn between each two points) in the point pattern is mapped onto every arc in the target point set. To reduce the search space, CAROL (Efrat *et al*., 2002) removes arcs by Delaunay triangulation of pattern subsets. The pattern is transformed by each candidate and the one with the shortest Hausdorff distance (the arc length of the worst spot match) is selected. The positions of subset matches are then used to locally transform the sample image before a global matching takes place.

It was not until recently that the processing power became cheap enough for pixel-based registration methods. Z3 (Smilansky, 2001) is a hybrid registration strategy where the two gel images are covered by small rectangles each containing a cluster of spots. As each sample rectangle is matched to the best reference candidate, a function constraining candidate selection is updated. This function defines a global transformation, which increases in complexity as more rectangles are matched. Once all rectangles have been processed, the sample image is warped by the final transform. The algorithm repeats on the transformed image until no further warping occurs.

Later, a direct registration algorithm with no recourse to detecting spots was proposed (Veeser *et al*., 2001). The control points of a bilinear or third-order B-Spline piecewise mapping are sought with the (BFGS) Broyden-Fletcher-Goldfarb-Shannon optimizer and the closed form derivative of a cross-correlation similarity measure. Convergence occurs as the gel images have smooth gradients, and therefore, the cross correlation with respect to the control points is smooth and continuous. To avoid local minima, a multiresolution approach is used,

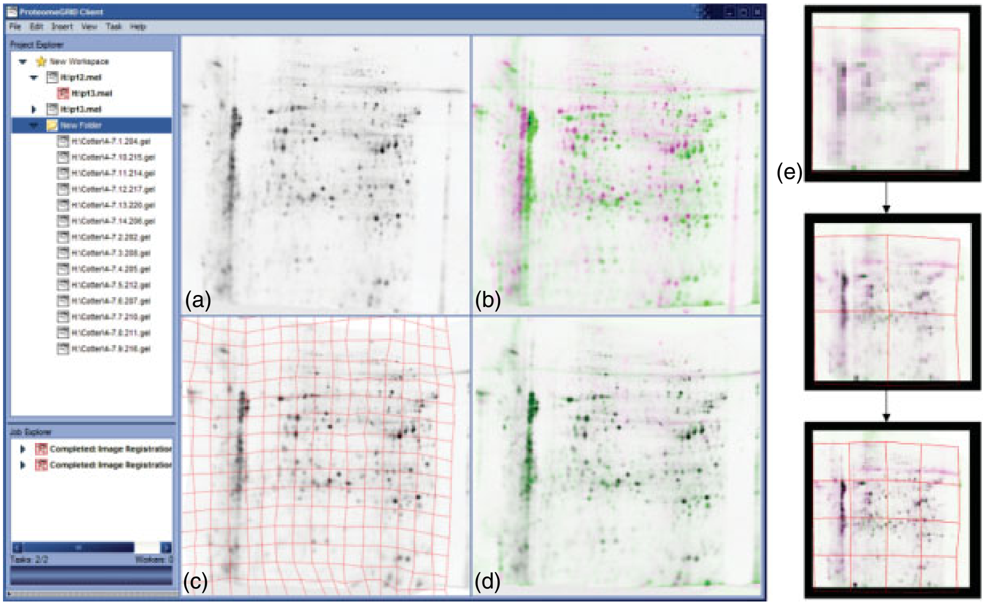

Figure 3 MIR image registration in the ProteomeGRID Client. (a) Control gel. (b) The control gel (magenta) overlaid on a treated sample gel (green). The geometric distortions are clearly evident. (c) The deformation mesh calculated by MIR. (d) The control gel overlaid on the transformed sample gel. (e) MIR searches for the global maximum and avoids local maxima by iteratively refining a course mesh on progressively higher resolution images

where the gel images increase in detail from 64×64 pixels to 1024×1024 as the mesh increases from 1×1 pieces to 16×16 (Figure 3).

Thus far, no software package attempts to correct for contrast variations. If we assume the inhomogeneities can be modeled by a smoothly varying multiplicative "bias field", which attenuates or amplifies intensity at each point, it can be corrected for without affecting true differential protein expression, which causes far more abrupt changes in intensity. Dowsey *et al*. (2003) demonstrated the shape-from-orientation approach as suitable for 2D gel analysis. An implicit thin plate spline surface is fitted to sparse orientation constraints (the ratio in integrated optical density IOD between spot matches) in a regularization framework.

5. Differential expression analysis

Without bias field correction, mutation detection requires robust statistical methods. Traditional methods are based on Student's T-test, the Mann–Whitney test, or Analysis of Variance (ANOVA). PCA can be used as an implicit bias field correction. The first component is interpreted as the bias field; the next few contain the most common volume changes over the set; and the rest are dominated by single spots and therefore indicate noise. However, if a particular model of activity is known, constraint analysis can be used to search the gel for spots satisfying the model constraints. Posttranslational modification, putative point mutations, and putative precursor product-pairs are examples of models that can be detected.

Once the differential expression is found, classification analyses are used to find intrinsic trends and relationships, that is, the intermixed reactions cells have to altered conditions. By utilizing prior results, classification also becomes a means to identify the unknown origin of tissue samples or the progression of disease or the efficacy of the treatment. Among the different techniques proposed, ChiClust (Harris *et al*., 2002) uses Ward's minimum variance method, where the sum of the squared distances from each member to the group centroid is used as an indicator of dispersion. Groups are joined only if the increase in this sum is less for that pair of groups than for any other. For time course experiments, Vohradsky (1997) first compared cluster analysis and cluster analyses to classify the stages of *Streptomyces coelicolor* growth, and then compared spot profile classification, PCA, cluster analysis, and artificial neural networks (ANN) in the detection of transition phase.

6. The statistical expression analysis (SEA) approach for large-scale analyses

With traditional techniques, symbolic representation of spots is determined at the very early stages of the processing pipeline. Although the early use of abstraction greatly simplifies data handling and management, once such a description is reached intrinsic errors, dependant on the spot modeling and matching algorithms used, are persistent throughout the subsequent processing steps. Current technologies cannot therefore provide a coherent and integratable workflow without extensive user interaction. In practice, if the analysis was modeled statistically and performed simultaneously between sets of technical replicates, small insignificant expression changes over one pair could become significant when reinforced by the same consistent changes in the others. This permits the creation of a database of probabilistic baselines, or "norms", which characterize confidence levels for protein expression under different experimental settings. Such evidence will build up a statistical formation model of 2-DE, which would then be mined to discover intrinsic trends, increase the acuity of new results and provide valuable feedback to 2-DE scientists on the sensitivity of their experiments.

The use of SEA offers the potential for developing an automated high-throughput proteomics pipeline, but the computational demands that image mining techniques bring requires the utilization of Grid technology and the development of specific imaging middleware, to ensure its success. The Grid, through the Globus Open Services Grid Architecture, offers seamless computational cooperation between thousands of commodity PCs and specialist equipment, such as automated spot cutters and mass spectrometers. The ProteomeGRID initiative (**http://www.proteomegrid.org/**) is realizing this ambition, and its *proTurbo* clustering technology (Dowsey *et al*., 2004) can already be employed on shared office and laboratory workstations to harvest spare capacity.

Short Specialist Review

Detecting protein posttranslational modifications using small molecule probes and multiwavelength imaging devices

Wayne F. Patton

Perkin-Elmer Life Sciences, Boston, MA, USA

1. Introduction

The marriage of advanced imaging instrumentation and small-molecule detection reagents has been crucial to inventing new capabilities in electrophoretic detection, especially in the realm of nonradioactive posttranslational modification analysis. Fluorescent total-protein stains, such as SYPRO Ruby dye (Molecular Probes), Deep Purple dye (Amersham Life Sciences), and the cyanine dyes of the DIGE analysis system (Amersham Life Sciences, *see* Article 30, **2-D Difference Gel Electrophoresis – an accurate quantitative method for protein analysis**, Volume 5), provide detection limits matching silver staining but offer significantly better dynamic range of quantitation and better compatibility with protein characterization techniques, such as mass spectrometry (Patton, 2002; Mackintosh *et al*., 2003). Accurate measurement of total protein amounts is fundamental to evaluating posttranslational modification changes, since it provides a denominator term, serving as a baseline for monitoring potential alterations; that is, the total protein measurement ensures that different samples are present in comparable amounts on the gel and aids in distinguishing between changes in the levels of posttranslational modification per unit protein compared with changes in protein expression levels without concomitant changes in the modification level. Typically, total protein staining is performed after detecting specific posttranslational modification.

2. Acquiring images

The introduction of fluorescent dye technology has played a pivotal role in spurring development of advanced imaging instrumentation, such as CCD camera-based multiwavelength imaging platforms, as well as gel scanners with multiple laser excitation sources (reviewed in Patton, 2000a,b). For example, the ProXPRESS 2D Proteomic Imaging System (Perkin-Elmer) is a sensitive imaging instrument

that enables the use of a wide range of fluorescent and colored dyes owing to its CCD camera and multiwavelength emission and excitation capabilities. The instrument's high-pressure xenon arc lamp provides broadband wavelength coverage and requires modest power, allowing visualization of the wide range of dyes commonly encountered in proteomics investigations, including Coomassie Blue, Amido Black, silver, colloidal gold, and the variety of fluorescent dyes now available. While the spatial resolution of conventional fixed CCD camera-imaging systems is typically inferior to laser-based gel scanners and photographic film, this problem is circumvented with the ProXPRESS instrument by mechanically scanning the CCD camera over the gel or blot and collecting multiple images that are subsequently automatically reconstructed into a complete image. Thus, the system readily delivers the same 50-μm spatial resolution obtained with high-end laser scanners, such as the FLA-5000 fluorescent imager (Fuji Corporation). By acquiring images in succession, as many as four different fluorescent labels may be viewed from any single gel.

3. Detecting posttranslational modifications

The rapid and comprehensive elucidation of protein posttranslational modifications is certainly one of the more important challenges facing the field of proteomics. Three prominent protein posttranslational modifications, glycosylation, phosphorylation, and S-nitrosylation are now readily detectable after polyacrylamide gel electrophoresis using commercially available kits and instrumentation. The basic principles of the detection schemes are summarized below.

3.1. *Glycosylation*

Alterations in glycosylation profiles arising in human cancer are known to contribute in part to the malignant phenotype observed downstream of oncogenic events (*see* Article 62, **Glycosylation**, Volume 6). A sensitive green-fluorescent glycoprotein-specific stain, Pro-Q Emerald 300 dye (Molecular Probes), detects glycoproteins directly in polyacrylamide gels or on polyvinylidene difluoride (PVDF) membranes. Pro-Q Emerald 300 dye is conjugated to glycoproteins by a periodic acid Schiff's base (PAS) mechanism using room-temperature reaction conditions. As little as 300 pg of α_1-acid glycoprotein (40% carbohydrate) may be detected in gels after staining with the dye, and a 500- to 1000-fold linear dynamic range of detection is obtained. A UV transilluminator-based imaging system is required to detect the stain, but a related stain, Pro-Q Emerald 488 dye, allows the detection of glycoproteins using visible light excitation sources. GlycoProfile III fluorescent glycoprotein detection kit (Sigma-Aldrich) also operates by a PAS-staining mechanism and is suitable for fluorescence-based detection of glycoproteins. The dye can detect roughly 150 ng of a glycoprotein in gels. Additionally, chemiluminescence-based approaches employing PAS labeling with digoxigenin hydrazide followed by immunodetection with alkaline phosphatase-conjugated antidigoxigenin antibody conjugated (DIG Glycan Detection Kit, Roche Molecular Biochemicals), or PAS

labeling with biotin hydrazide followed by detection with horseradish peroxidase-conjugated streptavidin (ECL Glycoprotein Detection kit Amersham Life Sciences) detect glycoproteins on electroblots with high sensitivity.

3.2. Phosphorylation

Reversible protein phosphorylation plays a critical regulatory role in the circuitry of biological signal transduction, and disregulation of this process is a hallmark of carcinogenesis (*see* Article 63, **Protein phosphorylation analysis by mass spectrometry**, Volume 6). Pro-Q Diamond phosphoprotein stain (Molecular Probes) detects phosphoserine-, phosphothreonine-, and phosphotyrosine-containing proteins on SDS-polyacrylamide gels, isoelectric focusing gels, 2-D gels, electroblots, and protein microarrays by a mechanism that combines a chelating fluorophore and a transition metal ion (Schulenberg *et al*., 2003). The staining is rapid, simple to perform, readily reversible, and fully compatible with modern microchemical analysis procedures, such as MALDI-TOF mass spectrometry. Pro-Q Diamond dye can detect as little as 8 ng of pepsin, a monophosphorylated protein. The linear response of the fluorescent dye allows rigorous quantitation of phosphorylation changes over a 500–1000-fold concentration range. Alternatively, phosphoproteins may be selectively detected in gels through alkaline hydrolysis of serine or threonine phosphate esters, precipitation of the released inorganic phosphate with calcium, formation of an insoluble phosphomolybdate complex, and then visualization of the complex with methyl green dye, as recently commercialized in the GelCode phosphoprotein detection kit (Pierce Chemical Company). Detection by the staining method is not particularly sensitive, however, with microgram to milligram amounts of phosphoprotein required to obtain a discernible signal. Phosphotyrosine residues cannot be detected with the stain.

3.3. S-nitrosylation

In an analogous manner as with protein phosphorylation, protein S-nitrosylation is thought to represent a key mechanism for the reversible posttranslational regulation of protein activity and, consequently, cellular function (*see* Article 68, **S-nitrosylation and thiolation**, Volume 6). Until relatively recently, the detection of protein S-nitrosylation in cells and tissues has been limited by a lack of appropriate detection techniques that permit identification of this labile posttranslational modification on target proteins. The Biotin Switch method was devised to facilitate the detection of protein S-nitrosylation after SDS-polyacrylamide gel electrophoresis and electroblotting (reviewed in Patton, 2002). The basic approach has been commercialized as the NitroGlo nitrosylation detection kit (Perkin-Elmer). The NitroGlo kit provides an optimized procedure for detecting protein S-nitrosylation that has been validated using known S-nitrosylated proteins, such as H-ras and creatine phosphokinase. Following chemical blocking of free cysteine residues, S-nitrosylated cysteine residues are reduced to free thiols. These free thiols are then modified with a biotinylating reagent. Thus, only the cysteine residues that had

nitroso modifications are tagged with a biotin label. Gel electrophoresis may then be performed to separate the various proteins in the sample. Alternatively, the labeled proteins may be selectively enriched using streptavidin affinity chromatography prior to gel electrophoresis. Western blotting, using chemiluminescence reagents, such as the Western Lightning kit (Perkin-Elmer), and subsequent imaging of the blots, generates a fingerprint pattern of the S-nitrosylated proteins in the specimen.

In conclusion, small-molecule-based detection molecules, in combination with advanced analytical imaging devices, now permit the routine monitoring of common protein posttranslational modifications in polyacrylamide gels and on electroblot membranes, without resorting to the use of hazardous radiolabeling approaches. Though these probes do not provide the same level of detection sensitivity as radiolabeling, they are safer and more convenient, allowing measurement of native posttranslational modification levels, as opposed to changes in levels associated with a particular labeling incubation time period employed in an experiment.

Short Specialist Review

Real-time measurements of protein dynamics

Caoimhín G. Concannon, Heiko Duessmann and Jochen H. M. Prehn
Royal College of Surgeons in Ireland, Dublin, Ireland

1. Introduction

In recent years, a variety of imaging-based techniques has been developed, enabling more advanced studies of protein function and has opened new windows into our understanding of key cellular functions ranging from gene expression, intracellular signaling pathways, and second messenger cascades. Central to these advancements has been the development of new imaging technologies, sophisticated computer software for image acquisition and analysis, but most importantly the discovery and cloning of the green fluorescent protein (GFP) from the jellyfish *Aequorea* (*see* Article 58, **Immunofluorescent labeling and fluorescent dyes**, Volume 5). The versatility of GFP-like proteins as intracellular molecular sensors stems from their intrinsic ability to form chromophores within live organisms, tissues, and cells without the requirement for any additional cofactors or substrates with the exception of molecular oxygen. Since these proteins are genetically encoded, this property can therefore be manipulated to create genetic fusions to any variety of protein sequences that can then be targeted to appropriate subcellular sites, enabling biochemical processes to be examined in real time using live cell imaging (Lippincott-Schwartz and Patterson, 2003). Molecular biology techniques have further aided the visualization of protein dynamics with the generation of mutants of GFP with blue, cyan, and yellow emission spectra (right up to the 529 nm emission maximum of yellow fluorescent protein, YFP) (Zhang *et al*., 2002). In addition, the discovery of "GFP-like proteins" from Anthozoa (coral) animals has further expanded the variety of colors available for multicolor labeling of different proteins. The most important of these are the red fluorescent proteins (RFPs) that possess emission maxima at wavelengths greater than 570 nm, an area of the spectrum where eukaryotic cells display reduced autofluorescence. DsRed, in particular, has several positive attributes such as impressive brightness and increased pH stability over GFP. However, it does have the problem that it is an obligate tetramer, which can limit its applications in terms of in vivo protein labeling. In this article, we will discuss several techniques that have been derived from GFP technology for the measurement of protein location and movement within living cells.

2. Visualizing protein dynamics during apoptotic cell death

We have utilized GFP technology to visualize the translocation of proteins involved in a form of cell death termed apoptosis. Central to the initiation of apoptosis is the release of several proapoptotic proteins, such as cytochrome *c*, from mitochondria. When released into the cytosol, cytochrome *c* forms part of a complex termed the *apoptosome*, which is involved in the activation of caspases, a group of proteolytic enzymes responsible for the execution of apoptosis. Using GFP-tagged cytochrome *c* and time lapse confocal microscopy, we can quantitatively visualize the translocation of cytochrome *c* from mitochondria by monitoring the redistribution of the fluorescent signal of GFP following the addition of an apoptotic stimulus (Luetjens *et al*., 2001). Cytochrome-*c*-GFP release during apoptosis is a surprisingly

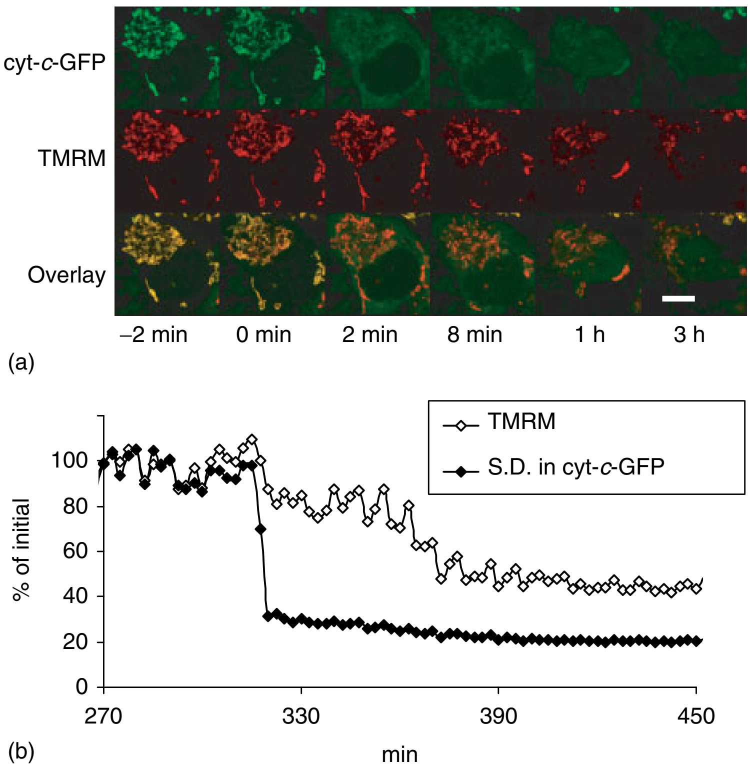

Figure 1 The release of cytochrome-*c*-GFP triggers a decrease in mitochondrial TMRM uptake. (a) HeLa D98 cells stably expressing cytochrome-*c*-GFP were equilibrated with 30-nM TMRM and treated with 3-µM STS. Cytochrome-*c*-GFP release was followed by a reduction in mitochondrial TMRM uptake. Bar, 10 µm. (b) Individual trace of the cell in (a). The release of cytochrome *c*-GFP was detected as a reduction in the standard deviation of the GFP pixel intensities of single cells. Changes in TMRM uptake were calculated from single cells by determining their average pixel intensity in the TMRM-sensitive channel. The onset of the decrease in mitochondrial TMRM uptake occurred simultaneously to mitochondrial cytochrome-*c*-GFP release, suggesting an irreversible mitochondrial membrane potential depolarization during the period monitored

rapid and coordinated process that can be quantitatively described by measuring the standard deviation of the average fluorescent intensity per pixel. In nonapoptotic cells, cytochrome *c*-GFP is compartmentalized within mitochondria, which contributes to a high standard deviation of pixel intensities (Figure 1). Upon its redistribution to the cytosol, its localization becomes more homogeneous throughout the cell, leading to a decrease in the standard deviation of pixel intensities. Measurements of protein dynamics can be combined with measurements of cellular functions using a variety of fluorescent probes such as potential- or redox-sensitive dyes (Dussmann *et al*., 2003). For example, the release of cytochrome-*c*-GFP is accompanied by a decrease in mitochondrial membrane potential that can be detected using the cationic probe TMRM (Figure 1). Studies of protein dynamics can also be combined with studies of protease activation or protein interactions detected by fluorescence resonance energy transfer (FRET) (*see* Article 51, **FRET-based reporters for intracellular enzyme activity**, Volume 5) technology. For example, we have delineated the temporal relationships between release of proapoptotic factors from mitochondria and caspase activation on a single cell level during apoptosis by combining GFP and FRET imaging (Rehm *et al*., 2003).

3. Fluorescence recovery after photobleaching (FRAP) and photoactivation

The visualization of the lateral mobility and dynamics of proteins within living cells with fluorescence recovery after photobleaching (FRAP) is facilitated with the introduction of improved scanning and laser light intensity regulation in point scanning confocal microscopes (*see* Article 53, **Photobleaching (FRAP/FLIP) and dynamic imaging**, Volume 5). Using this technique, a defined region of a cell is extinguished of fluorescence by a brief but intense excitation pulse, which is sufficient to irreversibly inactivate the fluorescent proteins within that defined area. The influx of new fluorescent proteins into the photobleached region is monitored over time with low-intensity laser light until a recovery plateau is achieved. This recovery of fluorescence results from protein diffusion or transport into the region of interest, and its quantification can provide valuable information about the kinetic properties of a particular protein within that compartment of a cell (Lippincott-Schwartz *et al*., 2003). If the protein is freely able to move within that compartment and the volume of the compartment can be assumed to be infinite compared to the bleached area, the fluorescence will recover to the levels of the prebleach values. Usually, a FRAP curve is fitted to the fluorescence recovery kinetics postbleaching. From this curve, it is possible to calculate the diffusion constant/transport rate, as well as the fraction of the protein that is mobile in that compartment. This information in combination with computer modeling can help resolve cellular pathways and has been successfully used to analyze protein transport pathways as well as measuring the dynamics of nuclear proteins.

Another method to visualize the movements of proteins within their native environment is to utilize the phenomenon of photoactivation. This method involves the use of GFP variants whose fluorescence is switched on or significantly increased

following activation with light of particular wavelengths. Currently, there are three readily available photoactivable fluorescent proteins – Kaede, KFP1, and photoactivatable-GFP (PA-GFP). Native PA-GFP has a major absorbance peak at 399 nm and an emission maxima at ~517 nm. However, following photoactivation at ~405 nm, a major new absorbance peak is observed at 504 nm, resulting in ~100-fold increase in its fluorescence at 517 nm. This technique has the distinct advantage of allowing the fluorescence of a protein to be switched on. Therefore, newly synthesized proteins will not fluoresce unless photoactivated and are unobserved, helping monitor the dynamics of proteins at particular time points. In this manner, using time lapse microscopy, it is possible to track both the movement and life span of proteins within cells. A disadvantage of the use of most photoactivatable fluorescent proteins is the requirement of intense light for photoactivation with relatively high photon energy levels. This requirement of short wavelength light from the visible spectrum might have detrimental effects on cells and is undesirable for live cell imaging. However, the development of new fluorescent proteins photoactivatable at longer wavelengths has great promise for the future use of photoactivation for measuring protein dynamics.

Basic Techniques and Approaches

Two-dimensional gel electrophoresis (2-DE)

Emma McGregor

Michael J. Dunn
Proteome Research Centre, University College Dublin, Conway Institute for Biomolecular and Biomedical Research, Dublin, Ireland

1. Introduction

The human genome contains fewer open reading frames (around 30 000 ORFs) encoding functional proteins than was generally predicted and, like all other completed genomes, contains many "novel" genes with no ascribed functions. Moreover, it is now apparent that one gene does not encode a single protein, because of processes such as alternative mRNA splicing, RNA editing, and posttranslational protein modification. Therefore, the functional complexity of an organism far exceeds that indicated by its genome sequence alone.

The concept of mapping the human complement of protein expression was first proposed more than 25 years ago (Anderson and Anderson, 1982), with the development of a technique in which large numbers of proteins could be separated simultaneously by two-dimensional polyacrylamide gel electrophoresis (2-DE) (Klose, 1975; O'Farrell, 1975), the term "proteome" not being established until the mid-nineties, defining the protein complement of a genome. Further details can be found in recent reviews (Dunn and Gorg, 2001; Rabilloud, 2002).

2. Two-dimensional gel electrophoresis (2-DE)

2-DE involves the separation of solubilized proteins in the first dimension according to their charge properties (isoelectric point, p*I*) by isoelectric focusing (IEF) under denaturing conditions, followed by their separation in the second dimension by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), according to their relative molecular mass (M_r). As the charge and mass properties of proteins are essentially independent parameters, this orthogonal combination of charge (p*I*) and size (M_r) separations results in the sample proteins being distributed across the two-dimensional gel profile (Figure 1). Achieving optimal separation of protein mixtures relies greatly on how the sample is handled and processed prior to 2-DE.

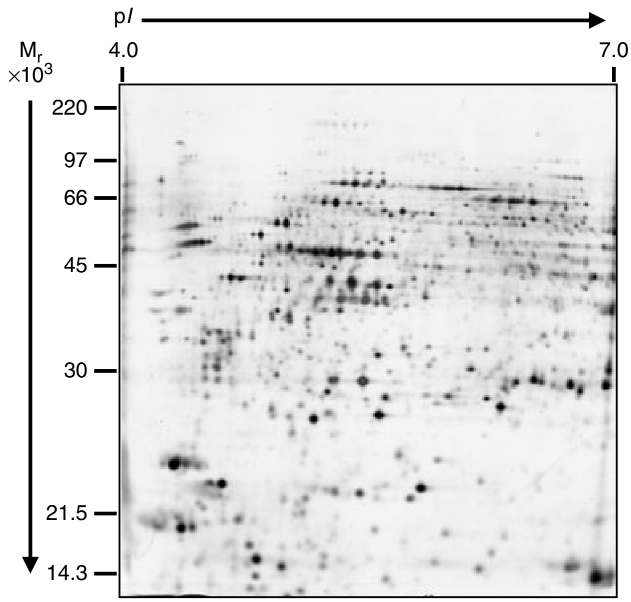

Figure 1 A two-dimensional electrophoresis (2-DE) separation of proteins solubilized from brain grey matter. The first dimension comprised an 18-cm nonlinear pH 4–7 immobilized pH gradient (IPG) subjected to isoelectric focusing. The second dimension was a 21-cm 12% SDS-PAGE (sodium dodecyl sulfate polyacrylamide gel electrophoresis) gel. Proteins were detected by silver staining. The nonlinear pH range of the first-dimension IPG strip is indicated along the top of the gel, acidic pH to the left. The M_r (relative molecular mass) scale can be used to estimate the molecular weights of the separated proteins

2.1. Sample preparation

Sample preparation is perhaps the most important step in a proteomics experiment as artifacts introduced at this stage can often be magnified with the potential to impair the validity of the results (*see* Article 2, **Sample preparation for proteomics**, Volume 5). No single method for sample preparation can be applied universally owing to the diverse nature of samples that are analyzed by 2-DE, but some general considerations can be mentioned. The high-resolution capacity of 2-DE is exquisitely able to detect subtle posttranslational modifications such as phosphorylation, but it will also readily reveal artifactual modifications such as protein carbamylation that can be induced by heating of samples in the presence of urea. In addition, proteases present within samples can readily result in artifactual spots, so that samples should be subjected to minimal handling and kept cold at all times, and it is possible to add cocktails of protease inhibitors.

2.2. Solubilization

Ideally, the solubilization procedure for 2-DE would result in the disruption of all noncovalently bound protein complexes and aggregates into a solution of individual

polypeptides. If this is not achieved, persistent protein complexes in the sample are likely to result in new spots in the 2-D profile, with a concomitant reduction in the intensity of those spots representing the single polypeptides. The method of solubilization must also allow the removal of substances, such as salts, lipids, polysaccharides, and nucleic acids as these can interfere with the 2-DE separation. Finally, the sample proteins must remain soluble during the 2-DE process. For these reasons, sample solubility could be viewed as one of, if not the most, critical factors for successful protein separation by 2-DE (*see* Article 22, **Two-dimensional gel electrophoresis**, Volume 5).

2.3. Isoelectric focusing (IEF)

Immobilized pH gradients (IPG) (Amersham Biosciences), generated using immobiline reagents, are now widely used, replacing the synthetic carrier ampholytes (SCA) previously used to generate the pH gradients required for IEF. The use of IPGs can achieve highly reproducible protein separations and have high resolution.

The IPG IEF dimension (first dimension) of 2-DE is performed on individual gel strips, 3–5-mm wide, cast on a plastic support. IEF is generally carried out using either an IPGphor (Amersham Biosciences) or Multiphor (Amersham Biosciences) apparatus. By applying a low voltage during sample application by in-gel rehydration (Rabilloud *et al*., 1994), improved protein entry, especially of high molecular weight proteins has been reported using the IPGphor (Gorg *et al*., 2000). However, an increased number of detectable protein spots in 2-D gels has been reported following IEF using the Multiphor compared to the same samples subjected to IEF using the IPGphor (Choe and Lee, 2000). Recently, the IPGphor was used for sample loading under a low voltage and the strips were then transferred to the Multiphor for focusing, with an increased sample entry compared to using the Multiphor alone being reported (Craven *et al*., 2002).

The most common IPGs used are those in the pH ranges of 3–10, linear, and nonlinear. However, intermediate (e.g., pH 4–7, 6–9) and narrow (e.g., pH 4.0–5.0, 4.5–5.5, 5.0–6.0, 5.5–6.7) range IPG IEF gels are now available and have the capability of “pulling apart” the protein profile, thus increasing resolution in particular regions of a gel. This “zoom gel” approach results in enhanced proteomic coverage (Westbrook *et al*., 2001).

2.4. Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE)

Following steady-state IEF, strips are equilibrated and then applied to the surface of either vertical or horizontal slab SDS-PAGE gels (the second dimension). Using standard format SDS-gels (20 × 20 cm) with 18 cm IPG strips, it is possible to routinely separate 2000 proteins from whole-cell and tissue extracts. Resolution can be significantly enhanced (separation of 5000–10 000 proteins) using large format (40 × 30 cm) 2-D gels. However, gels of this size are very rarely used owing to the handling problems associated with such large gels. The longest commercial IPG

IEF gels have a length of 24 cm. In contrast, mini-gels (7 × 7 cm) can be run using 7-cm IPG strips. While these gels will only separate a few hundred proteins, they can be very useful for rapid screening purposes. Second-dimension SDS-PAGE is usually carried out using apparatus capable of running simultaneously multiple large-format 2-D gels (e.g., Ettan DALT 2, 12 gels, Amersham Biosciences; Protean Plus Dodeca Cell, 12 gels, Bio-Rad). While such equipment allows large numbers of 2-D protein separations to be performed, the procedure is still very time consuming and labor intensive.

2.5. Protein detection and visualization

Following separation by electrophoresis, proteins must be visualized at high sensitivity (*see* Article 27, **Detecting protein posttranslational modifications using small molecule probes and multiwavelength imaging devices**, Volume 5). Appropriate detection methods should therefore ideally combine the properties of a high dynamic range (i.e., the ability to detect proteins present in the gel at a wide range of relative abundance), linearity of staining response (to facilitate rigorous quantitative analysis), and if possible, compatibility with subsequent protein identification by mass spectrometry.

Staining by Coomassie brilliant blue (CBB) has, for many years, been a standard method for protein detection following gel electrophoresis, but its limited sensitivity (around 100-ng protein) stimulated the development of a more sensitive (around 10-ng protein) method utilizing CBB in a colloidal form (Neuhoff *et al*., 1988). Since its first description in 1979 (Switzer, III *et al*., 1979), silver staining has often been the method of choice for protein detection on 2-D gels due to its high sensitivity (around 0.1-ng protein). Detection methods based on the postelectrophoretic staining of proteins with fluorescent compounds have the potential of increased sensitivity combined with an extended dynamic range for improved quantitation (*see* Article 27, **Detecting protein posttranslational modifications using small molecule probes and multiwavelength imaging devices**, Volume 5). The most commonly used reagents are the SYPRO series of dyes from Molecular Probes (Patton, 2000). However, more specialized fluorescent detection compounds are available, for example, Pro-Q Diamond and Pro-Q Emerald, used for the detection of phosphorylated and glycosylated protein isoforms respectively (*see* Article 27, **Detecting protein posttranslational modifications using small molecule probes and multiwavelength imaging devices**, Volume 5), and the fluorescent cyanine dyes, Cy2, Cy3, and Cy5 used in the staining procedure known as two-dimensional difference gel electrophoresis (DIGE) (Unlu *et al*., 1997; *see also* Article 25, **2D DIGE**, Volume 5 and Article 30, **2-D Difference Gel Electrophoresis – an accurate quantitative method for protein analysis**, Volume 5).

2.6. Protein identification

Mass spectrometry is used for routine protein identification in proteomics experiments as the associated methods are very sensitive, require small amounts of sample

(femtomole to attomole concentrations), and have the capacity for high sample throughput (Patterson and Aebersold, 1995; Yates, 1998; *see also* Article 31, **MS-based methods for identification of 2-DE-resolved proteins**, Volume 5). Peptide mass fingerprinting (PMF) is typically the primary tool for protein identification (*see* Article 3, **Tandem mass spectrometry database searching**, Volume 5). It is based on a set of peptide masses obtained by MS analysis of a protein digest (usually using trypsin) that provides a characteristic mass fingerprint of that protein (*see* Article 16, **Improvement of sequence coverage in peptide mass fingerprinting**, Volume 5). Identification of the protein is then achieved by comparison of the experimental mass fingerprint with theoretical peptide masses generated in silico using protein and nucleotide sequence databases. This approach proves very effective when trying to identify proteins from species whose genomes are completely sequenced, but is not so reliable for organisms whose genomes have not been completed. If it proves impossible to identify a protein based on PMF alone, it is then essential to obtain amino acid sequence information. This is most readily accomplished using tandem mass spectrometry (MS/MS), using either MALDI-MS with post-source decay (PSD) or chemical assisted fragmentation (CAF), MALDI-TOF-TOF-MS/MS or ESI-MS/MS triple-quadropole, ion-trap, or Q-TOF instruments (*see* Article 8, **Quadrupole mass analyzers: theoretical and practical considerations**, Volume 5, Article 9, **Quadrupole ion traps and a new era of evolution**, Volume 5, Article 10, **Hybrid MS**, Volume 5, and Article 31, **MS-based methods for identification of 2-DE-resolved proteins**, Volume 5) to induce fragmentation of peptide bonds.

3. Conclusion

The current array of proteomic techniques makes it possible to characterize global alterations in protein expression associated with the progression of many different human diseases; however, there is still no one method that can replace 2-DE and its ability to simultaneously separate and display several thousands of proteins from complex mixtures. Although there are disadvantages associated with 2-DE, for example, separation of hydrophobic and/or membrane proteins, 2-DE nevertheless remains the core technique of choice for the separation of complex protein mixtures in the majority of current proteomics projects.

2-D Difference Gel Electrophoresis – an accurate quantitative method for protein analysis

Edward Hawkins and Stephen O. David
GE Healthcare, Chalfont St., Giles, UK

1. 2-D DIGE

Two-dimensional polyacrylamide gel electrophoresis (2-DE) was first introduced in 1975 to separate complex protein mixtures (O'Farrell, 1975; Klose, 1975). It is a powerful technique allowing the simultaneous visualization of large portions of the Proteome (approximately 3000 spots per gel). Unfortunately, the issues of lack of reproducibility, sensitivity, and quantitative capabilities of conventional 2-DE have limited the use of this technique as a quantitative tool (Alban *et al*., 2003).

A group at the Carnegie Mellon University in Pittsburg first described a method that enabled more than one sample to be separated in a single two-dimensional (2-D) polyacrylamide gel, known as 2-D Difference Gel Electrophoresis (DIGE) (Unlu *et al*., 1997).

Two-dimensional difference gel electrophoresis (2-D DIGE) builds upon the 2-D gel electrophoresis technique to provide highly accurate quantitative capabilities that is not possible to easily achieve with traditional 2-DE.

2-D DIGE enables up to three protein extracts to be separated on the same 2-D gel. This is made possible through the labeling of each extract using spectrally resolvable, size- and charge-matched fluorescent dyes known as CyDye™ DIGE Fluors (Alban *et al*., 2003). The samples are labeled prior to electrophoresis, using either Cy2, Cy3, or Cy5, mixed together, and separated using conventional 2-DE. Gels are then scanned using a Fluorescence Imager, such as Typhoon variable mode imager, to visualize all samples on the gel and image analysis is then performed using specialized 2-D software known as DeCyder™ 2-D Differential Analysis Software.

2. Internal Standard: a reference sample in 2-DE

Multiplexing of samples in 2-D DIGE adds to 2-DE, the advantages of a reference sample commonly seen in microarray studies. This reference sample known as

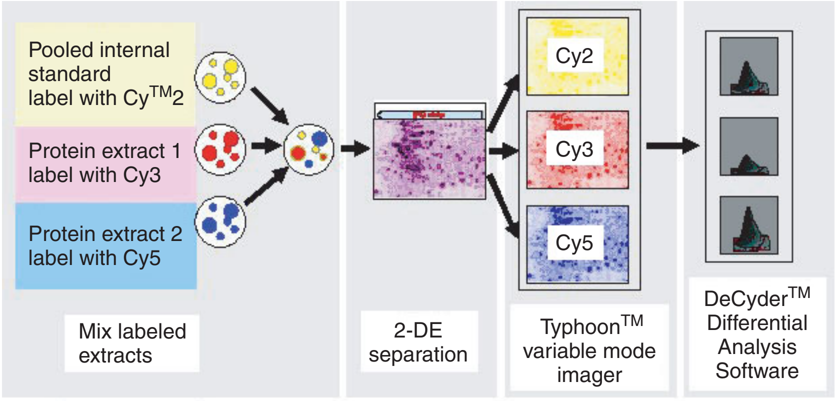

Figure 1 Principle of 2-D DIGE

the "Internal Standard" in 2-D DIGE is made of equal quantities of each of the biological samples being studied. Electrophoresis of the "Internal Standard" on each gel (see Figure 1) in the experiment along with the individual biological samples means that, the abundance of each protein spot on a gel can be measured relative (i.e., semiquantitatively as a ratio) to its corresponding spot in the internal standard present on the same gel.

Measurement of protein abundance as a "Standardized Ratio" instead of an "Absolute volume" greatly reduces the influence of experimental variation on the measured abundance of a protein spot on a 2-D gel. This reduction in experimental variation allows the detection and accurate quantitation of real biological expression changes free from the "noise" normally associated with experimental variation. This was demonstrated by Knowles *et al*. (2003) in a study that enabled them to accurately measure changes in protein expression as low as 10%.

Ettan™ DIGE is a complete system that has been optimized to fully benefit from the advantages provided by the 2-D DIGE technique.

3. Workflow

3.1. Labeling

The CyDye™ DIGE Fluors are Cyanine dyes and are supplied in two forms, CyDye™ DIGE Fluor minimal dyes (Cy2, Cy3, and Cy5) and CyDye™ DIGE Fluor saturation dyes (Cy3 and Cy5).

The "minimal" dyes react at pH 8.5 to specifically label the epsilon amino group of lysine residues. The ratio of dye to protein is kept very low (typically 50 µg of protein to 400 pmoles of dye) to ensure that the only proteins visualized are those labeled with a single dye molecule. This approach, referred to as "minimal labeling", ensures that the pattern seen on a 2-D gel is the same as that seen for a poststaining technique. The advantage of labeling lysine is that it is an abundant amino acid and is well represented in the total protein population (approximately

7.2% of all vertebrate proteins contain lysine). However, if this amino acid is not present in a protein, then this protein will not be visualized. This labeling approach requires approximately 50 µg of each protein sample to be loaded unto each gel and is suitable for situations where sufficient protein sample is available (e.g., Alban *et al*., 2003; Tonge *et al*., 2001; Zhou *et al*., 2002).

The "saturation" dyes react at pH 8.0 to specifically label the thiol group of cysteine residues, after an initial reduction step. The ratio of dye to protein is much higher (typically 5 µg to 4 nmoles of dye) to ensure that all the available cysteine groups are labeled. This approach is referred to as "saturation labeling". The lower proportion of proteins that contains cysteines (approximately 3.3% of all vertebrate proteins contain cysteines) in comparison to lysines in the total protein population means that some proteins visualized using the "minimal" dyes will not be seen using the "saturation" dyes. For this reason, the "minimal" dyes are used for general applications, while the "saturation" dyes are used for more specialized applications. The "saturation labeling" approach requires only approximately 5 µg of each protein sample to be loaded unto each gel and is ideal in situations in which only a small amount of protein is available. For example, samples obtained using techniques such as Laser Capture Microdissection. (Kondo *et al*., 2003)

3.2. Separation and imaging

Following separation of protein extracts on a standard two-dimensional (2-D) polyacrylamide gel, a Fluorescence scanner, for example the Typhoon™ 9000 series scanner, is used to scan the gels. The scanner has the ability to spectrally distinguish between the three CyDye Fluors, through the use of a combination of several lasers and filters. This enables the different samples on the same gel to be visualized individually.

3.3. Image analysis

The digital images generated by the imager can then be analyzed using an Image analysis software package, for example DeCyder™, that calculates the amount of fluorescence present in each spot. The DeCyder software utilizes proprietary algorithms to perform the unique form of image analysis required to accurately analyze the images generated using this technique, compared to standard 2-D image analysis. One such algorithm known as codetection generates identical spot detection on all images from the same gel. This method of detection decreases image analysis variation and increases accuracy in a manner that is not possible using standard image analysis algorithms. In addition, the presence of an internal standard on each gel enables gel-to-gel matching of all samples to be achieved through the matching of only the internal standard present on each gel.

Images from each individual gel are codetected in the DIA module of DeCyder (Figure 2). Gel-to-gel matching in the BVA module of DeCyder is achieved by choosing one of the internal standard images as a master image and then matching only the internal standard sample present on each gel to the master. After matching, proteins that are differentially expressed can then be identified.

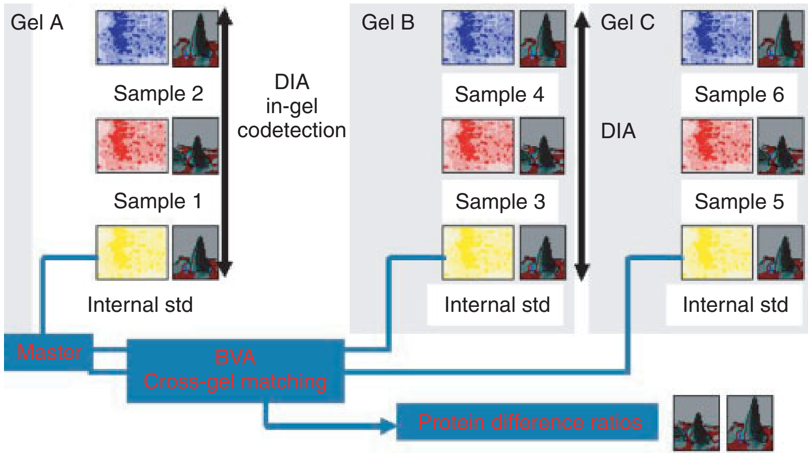

Figure 2 Codetection and matching

3.4. *Spot handling*

Following user confirmation of proteins of interest, a pick list of spots to be identified by mass spectrometry (MS) is then exported from the image analysis software to a spot excision robot. Spots can then be excised directly from a poststained analytical gel (if the gel contains sufficient protein for MS analysis) or from a separate post stained preparative gel. Picked spots are then digested and spotted for MS.

3.5. *2-D DIGE: a tool for proteomics*

Profiling proteomics involves the identification of proteins that are differentially expressed between biological samples or the identification of the protein complement in a sample. The sensitivity, broad dynamic range, reproducibility, and accuracy of quantitation obtained with 2-D DIGE makes this an ideal tool for proteome profiling.

Several proteomes have been successfully studied using this technique including those of bacteria, yeast, plants, fruit fly, insect, mouse and rat liver, rat kidney, rat heart, rat lung, cat brain, mouse and rat brain, guinea pig brain, human brain, and human cancer cells.

MS-based methods for identification of 2-DE-resolved proteins

Achim Treumann
Royal College of Surgeons in Ireland, Dublin, Ireland

Christopher Gerner
Medical University of Vienna, Vienna, Austria

1. Introduction

When O'Farrell (1975) and Klose (1975) published the first reports of separating and displaying complex protein mixtures on two-dimensional (2-D) gels (*see* Article 22, **Two-dimensional gel electrophoresis**, Volume 5 and Article 29, **Two-dimensional gel electrophoresis (2-DE)**, Volume 5) on the basis of isoelectric points and electrophoretic mobility, the research community rapidly adopted two-dimensional electrophoresis (2-DE) as the method of choice for the analysis of the protein content of tissues, cells, and organelles.

However, identification of the proteins in these 2-D maps posed a significant problem in the early years of 2-DE. The advent of new ionization techniques that were capable of generating ions of nonvolatile analytes and transferring them into the gas phase for mass spectrometric (MS) analysis invigorated the 2-DE research field. Matrix-assisted laser desorption ionization (MALDI) coupled to time-of-flight (TOF) detection (MALDI-TOF) (*see* Article 7, **Time-of-flight mass spectrometry**, Volume 5) and electrospray ionization (ESI) (*see* Article 18, **Techniques for ion dissociation (fragmentation) and scanning in MS/MS**, Volume 5) opened up the possibility of identifying and characterizing many proteins in a rapid and sensitive manner.

2. Peptide mass fingerprinting

2.1. Experimental

The most frequently used approach to protein identification from 2-D gels takes advantage of the relatively high purity of proteins in individual spots that are cut

out from 2-D gels. Peptide mass fingerprinting (PMF) is based on the realization that the masses of a number of peptides that are generated from one specific protein through sequence-specific proteolysis (frequently using trypsin, an enzyme that cleaves proteins after Arg and Lys) provide sufficient information for the unambiguous identification of this protein.

The following workflow is typical for PMF-based protein identification.

- A spot of interest is cut out from a gel and subjected *in-gel* to sequence-specific proteolysis.
- The resulting peptides are eluted from the gel and analyzed by mass spectrometry, most frequently by MALDI-TOF MS.
- These masses are then compared to datasets produced by in silico digestion of large numbers of proteins in a database. A score is calculated to assess the probability that the experimental dataset is derived from particular proteins in the database.

For high-throughput analyses, it is important that all of these steps can now be automated, significantly increasing the reproducibility and the speed of analysis.

MALDI is the ionization method of choice for PMF, due to its relatively higher tolerance of low-level contaminants when compared to ESI, to its high level of automation, and to its general combination with very sensitive and accurate TOF-detectors. The increased mass accuracy restricts the number of isobaric peptides in a database, and this greatly improves the stringency of the database search (Clauser *et al*., 1999).

2.2. *Data interpretation (search engines and algorithms)*

A large number of different search engines (**Mascot**, **Protein Prospector (MS-Fit)**, **ProFound**, **MassSearch**, **PeptIdent**) are available to perform the search of PMF data against a variety of different databases. Many of these provide free access through the Internet.

Generally, however, it is advisable to purchase a license for an in-house version of these search engines, as these will allow customization to the user's needs.

3. Peptide fragmentation

3.1. *Experimental*

Fragment ion spectra of peptides (*see* Article 3, **Tandem mass spectrometry database searching**, Volume 5 and Article 17, **Tutorial on tandem mass spectrometry database searching**, Volume 5) provide sequence information and are as a consequence far more informative than the mass of a peptide. Sequence from one single peptide can provide sufficient information for the unambiguous identification of the protein this peptide is derived from. As the accessibility of a sequenced genome is an essential prerequisite for the identification of proteins via

PMF, fragmentation spectra are the only way to identify proteins from organisms where ordered genomic databases are not yet available.

Whereas the initial stages of the workflow for protein identification by peptide fragmentation are identical to those for peptide mass fingerprinting (cutting spots out of a gel, *in-gel* proteolytic digest and elution of the peptide mixture from the gel), there are various ways of performing the subsequent MS analysis as follows.

- Post source decay (PSD) on a MALDI-TOF mass spectrometer. Because of limited sensitivity and difficult data analysis, this method is rarely used.
- LC-ESI-MS with collision-induced dissociation (CID) on an iontrap or a hybrid mass spectrometer (*see* Article 9, **Quadrupole ion traps and a new era of evolution**, Volume 5 and Article 10, **Hybrid MS**, Volume 5). When used for single spots from 2-DE, LC-ESI-MSMS is generally more time consuming than the acquisition of a mass fingerprint and it requires separate instrumentation from that used for PMF. However, it can be automated and it yields high-quality spectral information on peptides that can be chosen automatically during acquisition. Annotations of a majority of the spots in 2-DE gels have been performed using exclusively LC-coupled CID on hybrid mass spectrometers (e.g., O'Neill *et al*., 2002).
- Nanospray ESI-MS (*see* Article 11, **Nano-MALDI and Nano-ESI MS**, Volume 5 and Article 19, **Making nanocolumns and tips**, Volume 5). A separate aliquot of the digest is infused into a CID-capable mass spectrometer at very low flow rates (typically nl min^{-1}) through a metal-coated class capillary. Recently, a commercial device has been introduced that automates sample introduction at nanoflow rates, bypassing the difficult and time-consuming preparation and positioning of sample-filled glass capillaries (Van Pelt *et al*., 2002).
- MALDI-TOFTOF MS. Recently, new MALDI-TOF mass spectrometers have reached the market that permit the rapid and sensitive acquisition of peptide fragmentation spectra. For the purpose of protein identification from 2-DE spots, these mass spectrometers are the instrumentation of choice as peptide mass fingerprints, and peptide sequence information can be obtained unattended in one run on a single instrument.

3.2. Data interpretation (search engines and algorithms)

De novo interpretation of peptide fragmentation spectra is a lengthy and difficult task for which as yet no reliable computer algorithms have been developed. It is always necessary to check the output of computer-generated de novo sequences manually, which makes this unsuitable for high-throughput studies.

Several approaches have been developed to match peptide fragmentation spectra to peptide sequences from protein databases (*see* Article 3, **Tandem mass spectrometry database searching**, Volume 5 and Article 17, **Tutorial on tandem mass spectrometry database searching**, Volume 5). Independent of the choice of search engine, it is still advisable to check assigned spectra of intermediate quality manually to be confident of excluding false-positives.

4. Gel staining and MS response

Protein spots that are to be excised from a 2-D gel for the purpose of identification need to be visualized before the excision and digestion (*see* Article 27, **Detecting protein posttranslational modifications using small molecule probes and multiwavelength imaging devices**, Volume 5). It is essential that the staining of the gel is compatible with MS analysis and that it is sensitive enough to allow for the identification of a large number of proteins from a single gel.

Despite its relatively low sensitivity, colloidal Coomassie Brilliant Blue (CBB) staining is still one of the most popular staining methods in 2-DE-based proteomics studies. This is due to the simplicity of the staining procedure and to its excellent compatibility with MS-based protein identification. Any spots that are visible by CBB staining should be identifiable by MS-based analysis.

Silver-based staining is about 1 order of magnitude more sensitive than CBB staining, and MS-compatible silver staining methods have been developed (Shevchenko *et al*., 1996) and are in use in several proteomic laboratories around the world.

Fluorescence-based stains (Berggren *et al*., 1999; Rabilloud *et al*., 2001) provide excellent sensitivity and linearity for protein staining in gels, contributing to their superiority over silver-based staining methods, while also being compatible with MS-based protein identification.

5. Conclusions

Recent advances in sample preparation and analysis are addressing some of the drawbacks of 2-DE coupled with MS-based protein identification, in particular, the selectivity of 2-DE due to solubilization issues in the isoelectrophoretic dimension (leading to an underrepresentation of large, small, very acidic, very basic, and very hydrophobic proteins). The limited dynamic range of 2-DE-based experiments has been improved through careful experimental design and purification of subproteomes before analysis and through increased sensitivity of new mass spectrometers that have entered the market.

Proteome analysis through the 2-DE-based approach remains popular despite the development of several competing chromatography or chip-based technologies. This is due to the unsurpassed capability of 2-DE to display a large number of proteins from very complex mixtures, allowing for sample comparison and relative quantification. It is very likely that 2-DE coupled with MS-based protein identification will remain one of the mainstays of proteome analysis for expression profiling and for functional proteomics in years to come.

Arraying proteins and antibodies

David S. Wilson and Steffen Nock
Absalus Inc., Mountain View, CA, USA

1. Solid and suspension arrays

Two fundamentally different types of protein arrays (*see* Article 24, **Protein arrays**, Volume 5 and Article 100, **Protein microarrays as an emerging tool for proteomics**, Volume 4) are currently in use: (1) the classical two-dimensional (2D) array format and (2) encoded particle-based systems. Both types of arrays consist of distinct features onto which small amounts of certain proteins are immobilized. The distinction between 2D and liquid arrays consists in the manner in which the different features are "addressed" such that the identity of the immobilized protein can be deciphered. The features in 2D arrays are addressed spatially according to the arrangement used in dispensing the various molecules at known locations on a planar surface (*see* Article 90, **Microarrays: an overview**, Volume 4). The features in the liquid arrays, on the other hand, lose their spatial addresses since they consist of individual particles that, after being derivatized by proteins, are mixed together to form a suspension in a buffer. The addressing of the features in liquid arrays is achieved by encoding the particles optically in such a way that they can be "read" after being mixed together. The most common way to encode beads relies on the incorporation of different ratios of two or more fluorophores (Kettman *et al*., 1998). A flow cytometer is used to read particles one at a time, thus decoding the identity of each particle (and thereby the identity of the immobilized protein) while simultaneously reading the signal that is the object of the assay. The most popular suspension array platform is marketed by Luminex (Austin, TX). Some aspects of the different systems are compared in Table 1. Instruments and reagents are available commercially to allow researchers to construct their own 2D or suspension arrays, and ready-made arrays (*see* Article 33, **Basic techniques for the use of reverse phase protein microarrays for signal pathway profiling**, Volume 5) of both types are also available for certain important classes of proteins (cytokines, phospho proteins etc.).

2. Methods of protein immobilization

Proteins are very fragile molecules that are easily denatured at liquid–solid and liquid–air interfaces. All of these issues are significantly mitigated by using suspension arrays, but even in such cases, the nature of the substrates used for

Table 1 Comparison of multiplexed protein analysis platforms

	Two-dimensional arrays	Suspended particle arrays
Assay type	Direct capture, sandwich assay, functional assays	Direct capture, sandwich assay
Array construction method	Microspotting of all specificities onto each array	Batch incubation of particles followed by particle mixing
Detection (*see* Article 27, **Detecting protein posttranslational modifications using small molecule probes and multiwavelength imaging devices**, Volume 5)	Fluorescence, radioactivity, SPR, Mass spectrometry	Fluorescence
Multiplexing	High	Medium
Sample throughput	Low	High
Protein concentration required to saturate the surface	High ($\sim$1 mg ml^{-1})	May be done under dilute conditions
Storage	Dry	In buffer

protein immobilization will influence the protein density on the surfaces and the fraction of immobilized protein that is active.

Three fundamentally different approaches to protein immobilization have been described.

1. *Physical adsorption:* The most common and easiest method is to immobilize the protein via multiple noncovalent, heterogeneous linkages to the surface. The adherent forces are based on nonspecific adsorption onto hydrophobic surfaces such as plastics or gold, or onto charged surfaces such as naked or amine-derivatized glass, or nitrocellulose. When proteins come into contact with such surfaces, they spontaneously coat them to form a protein film. In such films, each protein is attached via multiple weak interactions (hydrophobic, electrostatic and van der Waals), but since the interaction surface on each protein is large, the sum of these weak interactions results in binding energies that are orders of magnitude stronger than typical "specific" protein–protein interactions, for example. The main disadvantage of these approaches is that, in order for a protein to make such extensive contact with the surface, it is often denatured. Generally, 75–90% of proteins attached to surfaces in this way are thought to be inactive (Butler *et al*., 1993).
2. *Random chemical attachment:* The second most popular and easy to use method is based on random covalent attachment of proteins. Typically, the surface is derivatized with an amino-reactive functionality such as *N*-hydroxy-succinimide, which then couples with the side chain amino group of lysines on proteins. Lysine is a common amino acid and its amino group is almost always on the surface of a folded protein. The number and positions of the attachment sites are heterogeneous, as is the orientation of the immobilized proteins. As a result, some fraction of the proteins will be inactive due to denaturation arising from strain caused by the multiple attachment sites or to modification of the actual binding or catalytic site. Random chemical attachment is the method

used for most of the suspension arrays, such as the Luminex system, and has also been used extensively for planar arrays (MacBeath and Schreiber, 2000). In some cases, the protein is attached indirectly to the surface through random biotinylation of the protein and use of streptavidin-coated surfaces (Peluso *et al*., 2003).

3. *Site-specific attachment:* The most elegant method for immobilizing proteins is by single-point attachment to an appropriate side chain on the protein surface. The most commonly used approach is to take advantage of a unique cysteine residue that is either naturally present in a protein or is introduced into a recombinant protein by genetic engineering. Surfaces can be derivatized by a number of thiol-reactive functionalities such as maleimide or haloacetamides. Under appropriate conditions, the coupling can occur almost exclusively through the unique thiol group, such that the immobilized proteins are homogenously oriented with respect to the surface. Several studies have demonstrated the superior performance of proteins immobilized by this type of method (see Peluso *et al*., 2003 and references therein). Recombinant proteins can also be specifically oriented onto surfaces by incorporating affinity tags such as the hexahistidine tag (Zhu *et al*., 2001). Site-specific chemical or enzymatic biotinylation can be used to orient proteins on streptavidin-coated surfaces (Peluso *et al*., 2003).

The choice of methods for immobilization depends highly on the application, the number and types of proteins that will be immobilized, and the sensitivity required for the assay. The larger the number of proteins to be immobilized, the more work is involved and hence simplicity is highly valued. The size and stability of the proteins is also very relevant. Unstable or small proteins are particularly susceptible to inactivation by immobilization through physical adsorption or random chemical attachment. For larger proteins, the likelihood that a particular protein will have its binding site, as opposed to another region of the protein, chemically or structurally modified is less likely.

Antibodies are very stable and large (150 kDa) molecules and hence activity is generally well retained upon random chemical attachment to surfaces. Noncovalent adsorption may also be used, but generally only 10–25% of the antibodies retain their activity under these conditions (Butler *et al*., 1993). For the best performance, antibodies can be immobilized in an oriented fashion through their carbohydrate groups on the Fc region, or by a more complex and less robust method that involves proteolytic processing and selective reduction of certain disulfide bonds (Peluso *et al*., 2003). While it is possible to engineer single cysteines into recombinant antibodies expressed in *Escherichia coli*, the production yields are typically too low to justify the added expense. Recombinant antibody fragments known as single-chain Fvs are notoriously unstable compared to larger fragments or intact antibodies.

3. Manufacturing arrays

Most of the devices for printing 2D arrays were originally developed for DNA spotting (*see* Article 91, **Creating and hybridizing spotted DNA arrays**,

Volume 4) and are not ideal for printing proteins. Printing methods are of two types – contact and noncontact. In contact printing, a tiny needle or capillary takes up a small amount of protein solution and contacts the array surface, thus transferring a sub-nanoliter volume (Haab *et al*., 2001). Contact printing can sometimes damage the substrate surface. Noncontact printing can be achieved with ink-jet technology (*see* Article 95, **Integrating genotypic, molecular profiling, and clinical data to elucidate common human diseases**, Volume 4), which allows picoliter volumes of protein solution to be applied to a surface without direct physical contact between the printing device and the array (Roda *et al*., 2000). A piezo-based printing device is currently marketed by Perkin-Elmer Life Sciences (Foster City, CA).

Both contact and noncontact-based printing, however, generally results in protein dehydration during the long serial printing process. This problem can be ameliorated by spotting the proteins in a humidified chamber and adding glycerol to the protein solution in order to prevent evaporation (MacBeath and Schreiber, 2000). Another option is to use hydrogel surfaces, which have the added advantage of supporting a higher density of protein per unit area on the array, due to the third dimension. This approach is reviewed by Mirzabekov and Kolchinsky (2002), and a commercial slide-based polyacrylamide is currently marketed by Perkin-Elmer Life Sciences (Wellesley, MA), which claims that the slides can immobilize antibodies at a density and activity capable of binding 13.5 pmol cm^{-2} of antigen. This density is five- to sixfold higher than can be obtained on optimized flat surfaces (Peluso *et al*., 2003). Using this novel hydrogel surface, a higher percentage of the immobilized protein was active than on flat polylysine-coated slides, and this translated to a higher signal-to-noise ratio (Miller *et al*., 2003).

The numerous difficulties in manufacturing reproducible, highly active 2D arrays (inconsistency in drop size and shape, protein denaturation at the liquid–air interphase, dehydration etc.) are irrelevant for the manufacturing of suspension arrays (Carson and Vignali, 1999). In the latter case, each protein solution is mixed with a single type of particle carrying a unique optical code. Protein-conjugated beads can be stored for over 1 year in suspension, so there are no dehydration issues. The different types of beads are then mixed together to create the suspension array. In the near future, there will be commercially available optically encoded magnetic beads, which will allow for high-throughput separations to be integrated into multiplexed protein detection assays.

Valerie S. Calvert and Emanuel F. Petricoin III
Center for Biologics Evaluation and Research, Bethesda, MD, USA

1. Introduction

At a functional level, cancer is both a proteomic and a genomic disease. A future in which the functional state of a large portion of the protein signal pathways within a patient's biopsy is analyzed could be realized within the next few years (Liotta *et al*., 2001; Petricoin *et al*., 2002; *see also* Article 96, **The promise of gene signatures in cancer diagnosis and prognosis**, Volume 4 and Article 100, **Protein microarrays as an emerging tool for proteomics**, Volume 4). A molecular network map of the state of key signaling pathways within a patient's tumor cells will become the starting point for a personalized and targeted therapy tailored to the individual tumor's molecular defect. Armed with the "wiring diagram" of the deranged cancer cell, it could be feasible to develop and administer a rationally selected combination therapy that targets multiple interdependent points along a pathogenic pathway, or targeting separate pathways. Following rebiopsy or molecular imaging, the effect of the treatment could be monitored in real time. In fact, an overarching goal for many investigators is to develop a "circuit map" of the cellular protein network (Blume-Jensen and Hunter, 2001; Bowden *et al*., 1999; Celis and Gromov, 2003; Hunter, 2000; Jeong *et al*., 2000; Charboneau, 2002; Chen *et al*., 2002; Cutler, 2003; Delehanty and Ligler, 2002; Ideker *et al*., 2001; Wilson and Nock, 2003; Zhu and Snyder, 2001; Zhu and Snyder, 2003; Huels *et al*., 2002; Humphery-Smith *et al*., 2002; MacBeath, 2002; MacBeath and Schreiber, 2000; Miller *et al*., 2003; Knezevic *et al*., 2001; Paweletz *et al*., 2001; Grubb *et al*., 2003; Wulfkuhle *et al*., 2003; Nishizuka *et al*., 2003a,b; Liotta *et al*., 2003; Roberts *et al*., 2004). Protein microarrays are especially well suited

for this approach since they represent an emerging technology that can detect many simultaneous posttranslational events in an extensively parallel mode, which is not possible using gene transcript profiling. Thus, protein microarrays offer an extremely attractive and complementary technology platform to existing expression profiling platforms (*see* Article 61, **Posttranslational modification of proteins**, Volume 6).

2. Classes of protein array technology

In general, protein microarray formats fall into two major classes: (1) forward phase arrays (FPA) and (2) reverse phase arrays (RPA), depending on whether the analyte to be measured is captured out of a solution phase or prebound to the solid phase (Figure 1) (*see* Article 24, **Protein arrays**, Volume 5). Using the FPA format, a capture or bait molecule, usually an antibody, is immobilized onto a substratum (e.g., derivatized glass, nitrocellulose, hydrogel). Each spot contains one specific and distinct immobilized antibody or bait protein. Using the FPA format, many hundreds to thousands of distinct bait molecules can be arrayed on a slide and each array is incubated with one test sample (e.g., a cellular lysate from one treatment condition). Conversely, the RPA format immobilizes an individual test sample in each array spot, such that an array is composed of hundreds of different patient samples or cellular lysates. In the RPA format, each array is incubated with one detection protein (e.g., antibody) and a single analyte endpoint is measured and directly compared across multiple samples.

3. Technical considerations

In contrast to gene microarray construction, the probes used (e.g., antibodies, aptamers, ligands, drugs) for protein microarrays cannot be directly manufactured with a priori predictable affinity and specificity. The availability of high-quality, specific antibodies or suitable protein-binding ligands is the single most limiting factor, and the starting point, for the successful utilization of protein microarray technology (Templin *et al*., 2002). Certainly, before using either RPA or FPA format, antibody specificity must be *thoroughly* validated. Each antibody to be used on an RPA is first analyzed on Western blot with suitable positive and negative controls and then a complex biological sample similar to that applied and analyzed on the array is analyzed. A significant challenge for protein microarrays in which a specific phosphorylation site is to be measured is the requirement for antibodies that are specific to the modification or activation state of the target protein. Fortunately, many sets of high-quality modification state–specific antibodies are commercially available, with many new phospho-specific antibodies becoming available monthly.

Most gene array platforms use planar silica substrata to immobilize the probes (Miller *et al*., 2002), and protein microarrays have used the same substrata and spotting equipment. While this approach may be successful for high abundant or recombinant analytes, a planar substratum may not be able to attain sufficient surface area per spot for femtomolar detection of analyte proteins in biologically

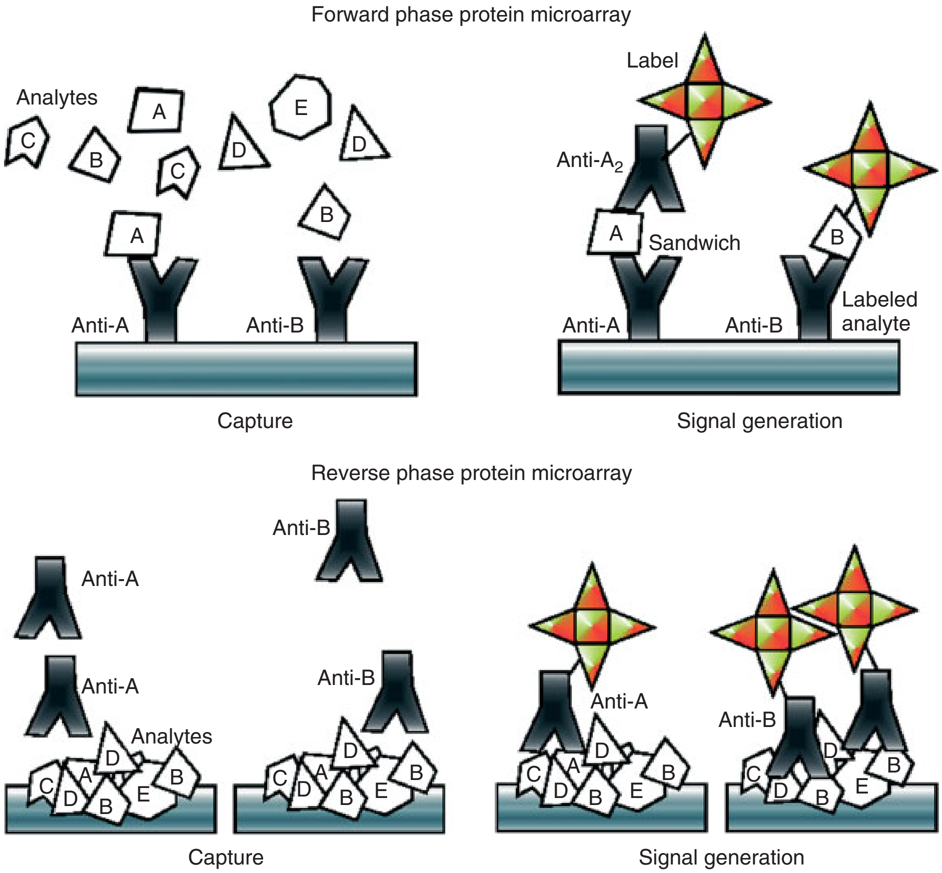

Figure 1 Classes of protein microarray platforms. Forward phase arrays (a) immobilize a bait molecule such as an antibody designed to capture specific analytes with a mixture of test sample proteins. The bound analytes are detected by a second sandwich antibody, or by labeling the analyte directly (a, right). Reverse phase arrays immobilize the test sample analytes on the solid phase. An analyte-specific ligand (e.g., antibody; b, left) is applied in solution phase. Bound antibodies are detected by secondary tagging and signal amplification (b, right)

relevant samples. Optimal substrata for protein microarrays must have high binding capacity, high surface area, and intrinsically low background signal (Seong, 2002). The choice of the substratum will dictate the immobilization chemistries employed. This, in turn, will impact on the native state, or on the appropriate orientation of the immobilized protein bait, or on the capture molecule.

4. Reverse phase arrays (RPA) for tissue analysis

We have developed RPAs as a format that appears to address many of the analytical challenges of detecting small levels of analytes (e.g., phosphorylated AKT) from very small amounts of input material (e.g., patient biopsy specimen) (Charboneau, 2002; Paweletz *et al*., 2001; Grubb *et al*., 2003; Wulfkuhle *et al*., 2003; Nishizuka

et al., 2003a,b; Liotta *et al*., 2003; Roberts *et al*., 2004; Zha *et al*., 2004) (Figure 2). This format has been successfully applied to analyze the state of the pro-survival, apoptosis and mitogenesis pathways within microdissected premalignant lesions, laser capture microdissected breast cancer, metastatic colorectal cancer, ovarian cancer, prostate cancer, follicular lymphoma, and lung epithelia exposed to different particulate toxicants (Charboneau, 2002; Paweletz *et al*., 2001; Grubb *et al*., 2003; Wulfkuhle *et al*., 2003; Nishizuka *et al*., 2003a,b; Liotta *et al*., 2003; Roberts *et al*., 2004; Zha *et al*., 2004). Each spot within an RPA contains an immobilized bait zone of solubilized and immobilized cellular lysate that measures only a few hundred microns in diameter. The high sensitivity of RPAs is due in part because the detection probe (e.g., antibody) can be tagged and the signal amplified, independent from the immobilized analyte protein. Third-generation amplification chemistries now available can be taken advantage of for highly sensitive detection

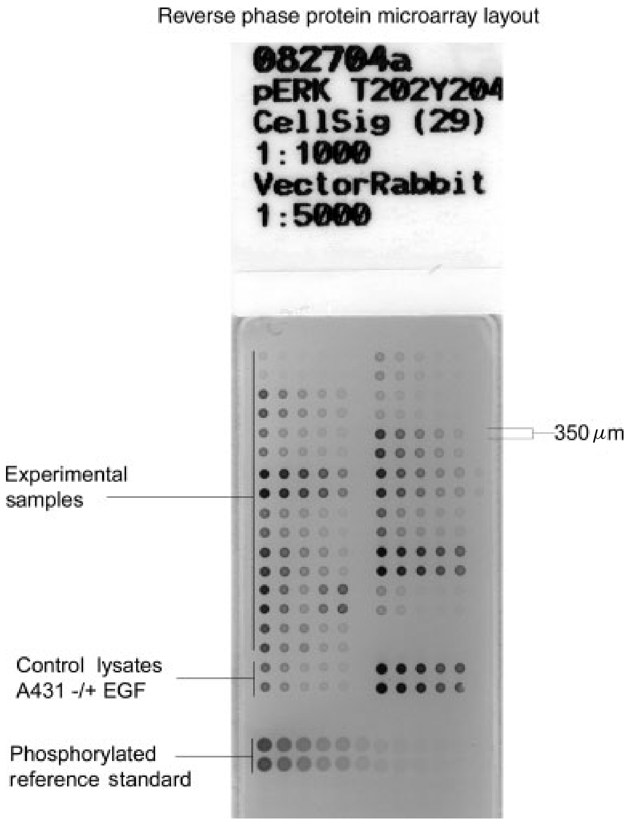

Figure 2 Idealized reverse phase array format. Duplicate samples are printed in dilution curves representing undiluted, 1:2, 1:4, 1:8, and 1:16 dilutions. The sixth spot represents a negative control, consisting of extraction buffer without sample. Each set of duplicate spots represents a patient sample before or after treatment, or microdissected normal, premalignant or stromal tissue cells. Positive and negative control reference lysates are printed on each array for monitoring assay performance. A reference standard, used as a conversion for experimental intensity values, is also printed on each array

(Hunyady *et al*., 1996; Bobrow *et al*., 1989; Bobrow *et al*., 1991; King *et al*., 1997). For example, coupling the detection antibody with highly sensitive tyramide-based avidin/biotin signal amplification systems can yield detection sensitivities down to fewer than 1000–5000 molecules/spot. A biopsy of 10 000 cells can yield 100 RPA arrays. Each array can be probed with a different antibody. Using commercially available automated equipment, RPAs exhibit excellent within-run and between-run analytical precision (3–10% c.v.) (Liotta *et al*., 2003). Moreover, RPAs do not require direct labeling of the sample analyte, which often destroys the epitope that is being detected, and do not utilize a two-site antibody sandwich, which often limits the repertoire of analytes that can be effectively measured. Therefore, there is no experimental variability introduced due to labeling yield, efficiency, or epitope masking. Even subtle differences in an analyte can be measured because each sample is exposed for the same amount of time to the same concentration of primary and secondary antibody and amplification reagents. RPA platforms can utilize reliable commercially available automated stainers designed for immunohistochemistry. Since each sample on the RPA format is applied in a "miniature dilution curve" on the array (Figure 2), in principle, a calibration curve is developed for each antibody, for each sample, and for each analyte concentration (Figure 3). This dynamic range analysis provides an improved means of matching the antibody concentration with the analyte concentration so that the linear range of each analyte measurement is ensured. The RPAs can be detected using a variety of protein array labels and amplification chemistries including fluorescent, radioactive, luminescent, and colorimetric read-outs (King *et al*., 1997; Kukar *et al*., 2002; Morozov *et al*., 2002; Schweitzer *et al*., 2002; Wiese, 2003).

5. Concluding remarks

RPAs may now provide a technological opportunity to elucidate and profile the ongoing protein phosphorylation levels in clinical specimens. The technical attributes of this type of array are amenable to small quantities of material, such as those obtained by laser capture microdissection. Using this format, many dozens of phospho-specific endpoints can be semiquantitatively measured using only a few thousand cells. In the future, we can envisage a time when cancer patient management is an exercise in patient-specific targeting of signaling networks using the information gleaned from these arrays. The information within the patient-specific profile could then be used to select an optimal suite of therapies best suited to the individual.

Introductory Review

Protein interactions in cellular signaling

Tony Pawson
Samuel Lunenfeld Research Institute, Toronto, ON, Canada

1. Interaction domains

Protein–protein interactions are frequently mediated by specific domains, that are typically composed of 30–150 amino acids, and have a modular design such that their N- and C-termini are juxtaposed in space (Kuriyan and Cowburn, 1997; Pawson and Nash, 2000). As a consequence, an interaction domain can be readily incorporated into a host polypeptide in a fashion that leaves its ligand-binding surface available to engage a target protein. Interaction domains often recognize short peptide motifs, and the binding properties of a particular domain can therefore be defined by examining its binding sites on physiological partners and by its ability to select specific sequences from degenerate peptide libraries (Songyang *et al.*, 1993). Understanding this lexicon of protein–protein interactions makes it possible to predict the complement of interaction domains and recognition motifs present in a given protein, and thus its potential to associate with other polypeptides, based purely on its primary amino acid sequence (Yaffe *et al.*, 2001; *see also* Article 45, **Computational methods for the prediction of protein interaction partners**, Volume 5). Although protein interactions are frequently much more complex, since they are dependent on protein conformation, this simple concept provides a useful bridge between genomic and proteomic data and a basis for subsequent experimentation (*see* Article 46, **Functional classification of proteins based on protein interaction data**, Volume 5).

A critical feature of dynamic cellular responses is that protein interactions are carefully regulated. Molecular interactions control critical activities such as cell proliferation, differentiation, survival, and adhesion, all of which are essential for normal embryonic development and the maintenance of adult tissues. It is therefore important that the relevant complexes only assemble in response to appropriate signals. This regulation is commonly achieved in two ways. First, many interaction domains only bind with significant affinity to their targets once these have been modified by posttranslational modifications, such as phosphorylation (*see* Article 63, **Protein phosphorylation analysis by mass spectrometry**, Volume 6), and the interaction is terminated once the binding partner is dephosphorylated. In addition, interaction domains often undergo intramolecular interactions that block

their ability to bind an external ligand; these internal interactions must be broken before a productive multiprotein complex can be formed (Groemping *et al*., 2003).

Most regulatory proteins possess multiple domains, and therefore have the potential to bind several different ligands. Such proteins can be composed exclusively of interaction domains, and therefore act to nucleate the formation of larger complexes (Pawson and Scott, 1997). They can also possess enzymatic domains, which are regulated and targeted to their substrates by their associated interaction domains. In either case, proteins can be viewed as being organized in a cassette-like fashion from several distinct domains. An additional point is that the same interaction and catalytic domains are found repeatedly in many different proteins, and are often present in hundreds of copies in the human proteome. Thus, a significant means through which functional diversity has been achieved during the course of evolution appears to be through the arrangement of interaction and catalytic domains into novel combinations, with new biological properties.

2. SH2 domains and phosphotyrosine signaling

The Src homology 2 (SH2) domain is the prototypic interaction module (Sadowski *et al*., 1986), and illustrates several of these points. SH2 domains are a common feature of an otherwise diverse set of cytoplasmic proteins that mediate the biological effects of growth factor receptors with tyrosine kinase activity, through their ability to directly recognize phosphotyrosine (pTyr)-containing sites. The Src SH2 domain, for example, binds phosphopeptide motifs with the consensus sequence pTyr-Glu-Glu-Ile, which adopt an extended conformation when associated with the SH2 domain (Waksman *et al*., 1993). The pTyr residue occupies a deep, positively charged binding pocket that is conserved among all SH2 domains. About half of the binding energy for the SH2-phosphopeptide interaction comes from recognition of the phosphorylated tyrosine, and as a consequence, the SH2 domain has negligible affinity for unphosphorylated sites. The peptide residues C-terminal to the pTyr occupy a second binding surface on the Src SH2 domain, which includes a hydrophobic pocket for the side chain of the Ile in the +3 position relative to the pTyr. This latter binding surface is rather variable among different SH2 domains, and as a consequence, each SH2 domain binds preferentially to a distinct phosphopeptide motif, depending on the nature of the amino acids following the pTyr. This selectivity imparts an element of specificity in tyrosine kinase signaling, which can be enhanced through the cooperative actions of multiple interaction domains. For example, proteins with two tandem SH2 domains, such as phospholipase-Cγ or the ZAP-70 intracellular tyrosine kinase, bind with increased affinity and specificity to motifs containing two adjacent pTyr motifs, as compared to a single SH2 domain-phosphopeptide interaction (Ottinger *et al*., 1998).

The full-length c-Src protein-tyrosine kinase associates with the plasma membrane through an N-terminal myristate group, and possesses SH3, SH2, and kinase domains. SH3 domains also mediate protein–protein interactions, most commonly by binding proline-rich sequences that adopt a polyproline type II helix (Waksman *et al*., 1993). In its autoinhibited state, Src is phosphorylated within its C-terminal tail by another tyrosine kinase (Csk), inducing an intramolecular

interaction between the SH2 domain and the phosphorylated C-terminus. This in turn promotes the association of the SH3 domain with the linker region between the kinase and SH2 domains. As a consequence of these intramolecular contacts, not only is the kinase domain locked in an inactive configuration but the SH2 and SH3 domains are also prevented from engaging another protein. Once this autoinhibitory embrace is disrupted, for example, by dephosphorylation of the tail, the SH3 and SH2 domains are released, and can guide the freshly activated kinase to its cellular substrates. Consistent with the importance of these intramolecular interactions in controlling enzymatic activity, deletion of the C-terminal tail renders Src oncogenic, as seen for the v-Src transforming protein (Martin, 2001).

Upon activation by the relevant growth factor, or following oncogenic mutation, receptor tyrosine kinases (RTK) cluster and become autophosphorylated at residues that potentiate kinase activity, usually by inducing a conformational change within the kinase domain. RTKs are also autophosphorylated at sites that lie in noncatalytic regions of the receptor, for example, in the C-terminal tail or in the region between the plasma membrane and the kinase domain. These phosphorylated motifs, in turn, serve as docking sites for the SH2 domains of cytoplasmic signaling proteins; the nature of the amino acids flanking each pTyr residue dictate which SH2-containing proteins will bind preferentially to that site, and thus determine the signaling output of a given receptor (Heldin *et al*., 1998; Schlessinger, 2000). The recruitment of an SH2-containing protein to an RTK can stimulate its function, and thus the activity of cytoplasmic signaling pathways, in a variety of ways. These include (1) relocalization to the plasma membrane and consequent juxtaposition next to its substrates; (2) conformational change induced by SH2 domain binding to the receptor, resulting in increased enzymatic activity; or (3) enhanced tyrosine phosphorylation once bound to the receptor, which can lead either to association with other proteins or to altered enzymatic activity (or both). Of interest, recent work has indicated that a subset of SH2 domains, as found in the protein APS, bind selectively to the phosphorylated activation segment of the kinase domain, and thereby directly regulate receptor kinase activity (Hu *et al*., 2003).

Among the proteins that interact with RTKs are scaffolding proteins such as IRS-1, Shc, or FRS2. These bind receptors through pTyr-binding (PTB) domains that recognize Asn-Pro-X-pTyr motifs. PTB domains are therefore similar to SH2 domains in the sense that they bind specific motifs in a pTyr-dependent fashion but, interestingly, are quite different from SH2 domains both in their structure and in their mode of phosphopeptide recognition (Forman-Kay and Pawson, 1999). This makes the point that multiple different domains can evolve to interact with related sequences. Once bound to the autophosphorylated insulin receptor, IRS-1 is phosphorylated at numerous tyrosine sites, which subsequently recruit SH2 domain proteins such as phosphatidylinositol (PI) 3′-kinase and the adaptor Grb2 (White, 1998). Thus, signaling pathways frequently proceed through an ordered series of modular protein–protein interactions.

Proteins with SH2 domains have diverse functions, and therefore allow RTKs to couple to a wide range of signaling pathways. These functions include the control of phospholipid metabolism, regulation of Ras-like GTPases, cytoskeletal organization, protein phosphorylation, and gene expression, amongst others. One possible explanation for the widespread use of interaction modules such as SH2 domains

is to facilitate the evolution of new signaling pathways. For example, existing evidence suggests that tyrosine kinases evolved to mediate cellular communication, and were therefore important for the development of multicellular animals. The simultaneous appearance of SH2 domains may have allowed preexisting proteins to immediately bind pTyr through the acquisition of an SH2 domain, and thus to serve as cytoplasmic targets of RTKs.

3. Protein–protein interactions: a common mechanism for signal transduction

Variations of the scheme outlined above for RTKs are employed by a wide range of cell receptors. As two of many examples, activation of the Fas cell-surface receptor activates a protease cascade that induces apoptotic cell death. Once oligomerized by its ligand, Fas signals through a cytoplasmic interaction domain, termed a *death domain* (Aravind *et al*., 1999; Strasser *et al*., 2000). The Fas death domain forms a heterodimer with the death domain of an adaptor protein, Fadd, which in turn binds through a death-effector domain to Caspase 8, a protease which initiates the apoptotic pathway. Although different in detail, this pathway is reminiscent of an RTK, which recruits the SH2 domain of the Grb2 adaptor. Grb2 binds through its SH3 domains to Sos, a guanine nucleotide exchange factor that stimulates the Ras GTPase to adopt an active, GTP-bound conformation capable of recruiting targets such as the Raf protein serine/threonine kinase (Pawson *et al*., 2002). In both cases, the activated receptor binds a modular adaptor, which then stimulates a signaling pathway, leading to a cellular response. This paradigm is also exploited by signaling pathways that emanate from intracellular cues. For example, double-stranded breaks in DNA recruit proteins that induce DNA-repair and cell cycle arrest. This DNA damage response involves the phosphorylation of signaling proteins on Ser/Thr residues, which are then recognized by interaction domains such as FHA or BRCT (as found in the tumor suppressor protein BRCA1) (Clapperton *et al*., 2004; Li *et al*., 2002; Yaffe and Elia, 2001).

4. Summary

Protein interactions, especially those mediated by dedicated interaction domains, can regulate a variety of biochemical processes that are critical for dynamic cellular organization, as follows:

1. Interaction domains can control protein subcellular localization. This is particularly evident for domains that bind to specific phospholipids, such as PH domains that can recognize phosphoinositides (PI), including PI-3,4,5-P_3 and PI-4,5-P_2. These domains can therefore target signaling proteins to selected membranes enriched in the relevant phospholipid.
2. Interaction domains can control dynamic cellular responses through their recognition of posttranslational protein modifications, such as phosphorylation, methylation, acetylation, hydroxylation, or ubiquitination (Pawson and Nash, 2003).

3. Distinct domains can be joined to create adaptor proteins, which link otherwise distinct proteins into a common signaling pathway (*see* Article 42, **Membrane-anchored protein complexes**, Volume 5).
4. As an extension of this concept, modular protein interactions can be employed in combination to yield multiprotein signaling complexes capable of sophisticated regulation (*see* Article 41, **Investigating protein–protein interactions in multisubunit proteins: the case of eukaryotic RNA polymerases**, Volume 5 and Article 42, **Membrane-anchored protein complexes**, Volume 5). An example involves PAR-6, which contains both PDZ and PB1 interaction domains, and mediates diverse interactions with protein kinases, scaffolding proteins, and GTPases. PAR-6 is the central component of a complex that controls numerous aspects of cell polarity (Macara, 2004).
5. Interaction domains, once joined to catalytic domains, can regulate both their enzymatic activity and the ability to select specific substrates.
6. The combinatorial use of protein–protein interactions can yield extended networks of proteins that are responsible for cellular organization (Giot *et al*., 2003; *see also* Article 38, **The *C. elegans* interactome project**, Volume 5, Article 39, **The yeast interactome**, Volume 5, and Article 44, **Protein interaction databases**, Volume 5).
7. Aberrant protein–protein interactions can result in the deregulation of signaling pathways, and thus in diseases such as cancer.

Introductory Review

Structural biology of protein complexes

Gabriel Waksman
Birkbeck and University College, London, UK

The formidable advances in protein sciences in recent years have highlighted the importance of protein–protein interactions in biology. Before the proteomics revolution, we knew that proteins were capable of interacting with each other and that protein function was regulated by interacting partners. However, the extent and degree of the protein–protein interaction network was not realized. It is now believed that not only a majority of proteins in an eukaryotic cell is involved in complex formation at some point in the life of the cell but also that each protein may have on an average 6–8 interacting partners (Tong *et al*., 2004).

The study of the structure of protein–protein complexes predates the proteomics revolution. The pioneering work on antigen–antibody and protease–protease inhibitor complexes has provided insight into protein–protein interfaces and their properties (Ruhlmann *et al*., 1972; Amit *et al*., 1986). However, more recently, the structure of larger complexes that function as molecular machines has been determined, shedding light into important cellular functions such as transcription (the structure of the RNA polymerase II core complex (Cramer *et al*., 2001)), translation (the structure of the ribosome (Ban *et al*., 2000; Wimberly *et al*., 2000)), replication (the structure of the γ-complex in bacteria (Jeruzalmi *et al*., 2001)), or the cytoskeleton (the structure of the Arp2/3 complex (Robinson *et al*., 2001)), to cite only a few. It is not the purpose of this short specialist review to make an exhaustive list of all protein–protein complexes, the structure of which has been determined to date, but instead to provide general concepts on the common and distinctive features of protein–protein interfaces and their roles.

Protein–protein interactions can be classified into approximately three subtypes, depending on their stability and the mode of interactions. Although any one protein may be involved in interactions with many others, they may form stable interactions only with a few. These form core-complexes, which are stable, can be purified, and are amenable to structural studies. A number of core-complex structures have been determined, and these structures have been instrumental in understanding how these core-complexes carry out their functions (see list above). A second category of interactions are transient, and the proteins involved in transient associations are often regulatory proteins, the role of which may be to confer short-lived, physiologically regulated, properties to other proteins or to core-complexes. The complexes that proteins form transiently

may be unstable and difficult to purify. Successes in determining the structure of transient complexes have been dependent on the affinity of the various constituents participating in complex formation. One historical breakthrough in this regard has been the determination of the structure of the first antigen–antibody complex (Amit *et al*., 1986), which defined the architecture and chemistry of protein–protein interactions in this versatile structural framework. Finally, protein–protein interactions in core-complexes or transient ones may be mediated by specialized, small, domains dedicated to protein–protein recognition (Pawson and Scott, 1997). In this review, interactions mediated by specialized domains are treated separately as their functions and roles have been studied in great details.

Protein–protein interfaces have been analyzed thoroughly in studies that have emphasized their high degree of versatility and plasticity (Jones and Thornton, 1996; Lo Conte *et al*., 1999). This is, in part, due to the fact that protein–protein interactions encompass a wide range of affinities. However, even within a particular range of affinities, the structural features underpinning binding may vary. For example, protease inhibitors appear to use main chain–main chain interactions, whereas antigen–antibody interaction is mediated by side chain–side chain interactions (Jackson, 1999). Side chain–side chain interactions may be more likely to determine specificity. In contrast, serine proteases must bind tightly to their target proteases. This may be best achieved using constrained “main chain–main chain” conformation, and means that the inhibitor will be highly committed to the enzyme. Similar observations corresponding to similar requirements have been observed in the interaction of pilus subunit with bacterial chaperones (Choudhury *et al*., 1999; Sauer *et al*., 1999). Proteins may be able to use the same template for interactions with different proteins or with different parts of the same protein. For example, in the growth hormone/growth hormone receptor complex (GH/GHR), two receptor molecules bind to different parts of the same ligand (de Vos *et al*., 1992). This complex structure and the subsequent site-directed mutagenesis studies have defined an important concept in protein–protein interaction, that of “hot spot” (Clackson and Wells, 1995). In the protein–protein interface observed in the GH/GHR complex, although a myriad of hydrogen bonds, van der Waals contacts, and electrostatic interactions is observed, only a limited few of these interactions have been shown to play an important role in binding. Similar observations have been made in other systems (Dall’Acqua *et al*., 1996; Bradshaw *et al*., 1999). One important property of protein–protein interfaces is the shape complementarity between the two regions coming together in the interactions. Remarkably, such complementarity is very often mediated by water molecules, judiciously placed at the interface to fill in holes and increase contacts (Bhat *et al*., 1994; Lubman and Waksman, 2003). The role of water in both the structural and thermodynamic basis of protein–protein interactions is essential and yet very poorly understood.

One remarkable feature of protein–protein interactions is that they are often mediated by small domains that specifically bind small sequence motifs on proteins. The Src-Homology 2 (SH2) domain was the first such domain to be recognized (Sadowski *et al*., 1986). SH2 domains are involved in the building up of large complexes at and around signaling receptors. SH2 domains bind specifically

sequences containing phosphorylated tyrosines and are able to discriminate between tyrosine-phosphorylated sites by exercising some preferences for residues located C-terminally relative to the phosphotyrosine (Bradshaw and Waksman, 2002). Since the discovery of SH2 domains, a large number of protein domains with specialized roles in protein–protein interactions have been found (see **http://www.mshri.on.ca/pawson/domains.html** for an exhaustive list of such domains). SH3 and WW domains specifically recognize and bind sequence motifs containing prolines (Musacchio, 2002). Proline-rich motifs are among the most common motifs identified, and thus SH3 and WW domains play major roles in protein–protein interactions. PDZ domains are essential for the integrity of the postsynaptic density, a large protein complex formed around glutamate and NMDA receptors in the nervous system (Sattler and Tymianski, 2001). Finally, bromodomains are similar to SH2 domains in that both bind (and thus induce recruitment of proteins that contain them) to sites of protein modifications. Bromodomains, unlike SH2 domains, which bind to tyrosine-phosphorylated sites, bind specifically acetylated lysines, and thus play important roles in chromatin remodeling during transcription and replication (Dhalluin *et al*., 1999).

There is no unifying theme among the structures of the protein–protein interaction domains listed above. However, as their structures have been characterized, intense efforts have been devoted to designing specific binding inhibitors capable of disrupting protein–protein interaction mediated by these modules. For example, the SH2 domain of the Src kinase has been targeted for molecular design and binding competitors able to inhibit osteoclast function have been found (Sawyer *et al*., 2002). As the major phenotype in Src knockout mice is a thickening of the bones, it is hoped that an Src SH2 domain–binding inhibitor could be used to combat osteoporosis, a devastating disorder in elderly women.

Using peptides or peptide mimics to disrupt protein–protein interfaces is not a novel idea but this approach has benefited from structural information. Notably, the molecular design of rigid peptido-mimetics is believed to greatly enhance the potential of peptides as therapeutics by not only locking the peptide in a defined binding conformation but also by preventing or slowing degradation (Patani and LaVoie, 1996). However, peptides or peptide-based compounds do not readily cross the cell barriers, and thus are not as effective as hoped. Recently, a peptide derived from the NR2 chain of the NMDA receptor known to interact with the second PDZ domain of PSD95, an essential component of the postsynaptic density, was made effective in reducing cerebral infarction in rats subjected to transient focal cerebral ischemia by fusing it to the HIV1-Tat translocator peptide (Aarts *et al*., 2002). Thus, the use of translocator peptides may be a promising avenue of research for the delivery of therapeutic peptides or proteins (Becker-Hapak *et al*., 2001).

In the next few years, we will see more of the core-complexes being tackled for structural studies. The methods to overexpress and purify them in large quantities are in place and it may just be a matter of time before their structures are determined. It will be more difficult to tackle the transient complexes involving proteins exhibiting only low affinity for each other. These may require the development of novel cross-linking or tethering methods, capable of capturing the complex as it forms.

Specialist Review

Biochemistry of protein complexes

Bertrand Séraphin
Centre for Molecular Genetics, Gif sur Yvette, France

1. Introduction

Proteins are quantitatively more abundant than RNA and DNA in average bacterial or eukaryotic cells. However, this abundance is contrasted by the extreme variation in the relative abundance of individual proteins: some being represented by several million of molecules in a given cell (such as hemoglobin in erythrocytes), while for others only a few molecules may be present at a given time. (This can go down to even less than one protein per cell when averaged on time.) This skewed distribution diversity is obviously not encountered for genomic DNA but is already partly apparent at the mRNA level.

Chemically, proteins are also more diverse than nucleic acids (*see* Article 96, **Fundamentals of protein structure and function**, Volume 6). This results from their assembly from over 20 amino acids that have significantly more diverse chemical and physical properties than the four bases present in DNA or RNA. Amino acids diversity can be further expended by numerous reversible or permanent posttranslational modifications. These amino acid properties direct the folding of proteins in a wide variety of tri-dimensional structures that contrast with the monotonous helical structure of B-type double stranded DNA. (Again, at this level, RNA appears to have intermediate properties between DNA and proteins by its number of possible natural structures.) The shape taken by proteins upon folding allow them to present an extreme diversity of surfaces that have been exploited by biological organisms to govern recognition and interaction of proteins with virtually any other type of chemicals: from water to small enzymatic substrates, from membrane to antigens, from DNA to proteins themselves. It is thus not surprising to observe that most proteins in a given cell do not exist as monomers but associate rather with other proteins to form large assemblies. Understanding cell function requires deciphering the network created through protein–protein interactions. This task is, however, difficult because, as indicated above, some proteins are poorly abundant while other polypeptides are embedded into biological membranes and thus difficult to handle. This is further complicated by the fact that some interactions are transient. Thus, it is not surprising that many techniques have been developed to analyze protein interactions. Some rely on indirect observation of the consequences

of protein interaction (e.g., two-hybrid assays (Fields and Song, 1989), fluorescence resonance energy transfer (FRET) (Wouters *et al*., 2001; *see also* Article 43, **Energy transfer–based approaches to study G protein–coupled receptor dimerization and activation**, Volume 5 etc.), while others detect directly the interaction between the protein factors (e.g., GST pull downs (Kaelin *et al*., 1991), coimmunoprecipitation (Lane and Crawford, 1979), or biochemical purifications (Deutscher, 1990)). In this review, I will focus on the biochemical methods that have been developed for the analysis of protein complexes.

2. A variety of complexes

The term "complex" needs to be defined as it encompasses many different meanings. I will refer here to complexes as a group of associated proteins that can be characterized biochemically. This definition has several implications: while a complex contains several polypeptides, they may be identical (homomeric complex) or they may represent at least two different sequences (heteromeric complex). Furthermore, the operational definition of complexes as entities that can be purified biochemically does not make any assumption about the stability, size, or biological function of the complex. Thus, a complex displaying an extreme stability in vitro may represent a transient intermediate in a biochemical pathway in vivo. In contrast, a very important biological complex may be too unstable to withstand conditions encountered during biochemical purification. In the same vein, a complex obtained following extensive purification may only represent a small unit resulting from the breakdown of a large molecular machine that carries the real biological activity in vivo. Further complication results from the heterogeneity in protein levels and affinity: the mass-action law indicates, indeed, that it may be possible to recover significant amount of a low-affinity complex formed by highly abundant proteins, while an intrinsically more stable assembly formed by extremely low abundance factors may dissociate under the same conditions preventing its purification. It is also clear that additional specific assays are required to test the function of protein complexes. However, while the practical definition of complexes as biochemically purifiable units suggests that the corresponding polypeptides interact in vivo, this needs to be ascertained and the physiological relevance of the interaction needs to be demonstrated as well. Indeed, it is not uncommon to find (highly abundant) proteins associated nonspecifically with a protein of interest. These "contaminants" may result from artifactual interactions induced by the experimentalist during protein extraction and purification (e.g., aggregation promoted by partial denaturation) to natural interactions that are not related to the process of interest (e.g., interaction of a protein with a chaperone may be relevant to complex assembly but not to the biological function of the protein itself). In this context, it is worth remembering that many protein interactions are transient and dynamic. Protein extraction and purification will block this dynamic in a certain number of states, resulting in the accumulation of proteins in a specific set of complexes. This distribution may differ significantly from the natural distribution of the corresponding factor. An additional bias may be introduced during complex purification: while two entities may be present in equimolecular amount, one may be efficiently recovered while the

other will be recovered in low amount. This bias, which often results from intrinsic chemical and/or physical property of the different entities, may further distort the relation between the observed complexes and the "real" biological situation present in vivo. Despite these limitations, biochemical analysis remains an essential tool for protein complexes analysis. Indeed, this strategy allows for a direct observation of protein complexes and thus determination of a wide variety of parameters that cannot be determined in many other types of experiments. For example, biochemical approaches permit the determination of complex stoichiometry, reveal the presence of posttranslational modification, isoenzyme or splice variant, allow the possibility to perform activity tests and/or determine affinity constants, and so on. Biochemical purification of a complex may even lead to the determination of the complex structure. Biochemistry of complexes benefits from the high synergy involved in complex formation in vivo. Many experiments have indeed revealed that pairwise interactions between subunits of a complex are often weak but that the whole assembly is stabilized through the synergistic network of associations occurring when all subunits are present simultaneously. This feature, that may be essential for the correct assembly of protein complexes in vivo, may be responsible for a high number of false-negative results in studies of protein interaction relying on simple binary tests (such as FRET studies and standard two-hybrid assays). However, as stated above, the mere finding of several proteins associated together is far from proving that this complex exists in vivo and additional analyses are, in each case, required to demonstrate the validity and functional significance of the proposed interactions.

3. Defining a target and a protein source

At least, two entry points are required for the biochemical analysis of protein complexes. First, the knowledge of at least one characteristic "target" of the complex to be analyzed is needed. In the early days of biochemistry, this "target" was often a biochemical activity. With the development of molecular biology and the availability of numerous genomic and cDNA sequences, this "target" can also be a predicted protein sequence. In other cases, antibodies directed against one or several polypeptides have been used. The characteristic "target" will be essential for the development of an appropriate purification strategy and may be the basis for specific activity assay. Beside the essential knowledge that defines the "target", one requires a source of proteins. The two major possibilities are the original host or recombinant proteins. Natural sources present the obvious advantage of being biologically relevant. Thus, protein complexes recovered from the original host will certainly provide significant information. Furthermore, no assumption needs to be made on the nature and the number of subunits present in the target complex when it is isolated from the natural host. The main problems encountered in analyzing protein complexes recovered from such a source are the purity and the limiting quantity of the starting biological material. If it is indeed easy to get large amounts of a homogeneous population of a cultivable unicellular organism, it may be difficult to recover sufficient material if the target protein is expressed in a few cells from a complex multicellular plant or animal. A similar problem is encountered if the proteins of interest are present in a single-cell organism

that cannot be grown in the laboratory and/or that is only present in a complex community of species. One can sometimes bypass the problem encountered with a multicellular organism as homogenous cell lines may provide a suitable source for biochemical purification of specific complexes. In the latter case, however, the results may represent the bona fide biological situation of the cell line but may only have a partial significance for the whole organism. Indeed, in the cell line, the complex structure and/or function may be altered in the absence of cues emanating from neighboring cells and/or hormonal signals originating from distant tissues. Additional complications related to the quantity and homogeneity of the starting biological material may be encountered if the complex is only transiently expressed or assembled. For example, it is easily understandable that difficulties will arise if low levels of the target complex are only transiently expressed during a very short time window of the cell cycle even if large amounts of nonsynchronized cells are easily produced. A further level of complication may arise if the protein is simultaneously present in different complexes in the starting biological material and/or if variants (e.g., as a result of alternative splicing) of the target factor do coexist. Most of the problems linked to the quantity and homogeneity of the starting biological material encountered with natural source of proteins can be bypassed if the complex is produced in a recombinant form. This strategy requires, however, the previous knowledge of the complex composition, the availability of clones containing the corresponding coding sequences, and the possibility to express efficiently the various subunits. In addition, effective complex assembly should occur in vivo if the subunits are coexpressed or in vitro if individual proteins are produced. Beside the requirement for the knowledge of the protein complex composition, additional difficulties encountered with the production of recombinant complexes often result from non- or low-expression of one or more subunit, lack of posttranslational modification(s), and absence of suitable condition for complex reassembly. If successful, this approach provides, however, large quantities of homogenous material perfectly suited for studies such as structure determination. In addition, the recombinant factors can easily be modified by standard genetic engineering methods and the consequences of these modifications on complex structure and/or function can easily been assayed.

4. Protein complex purification

Once a source of proteins and the target have been defined, a strategy for the purification of the complex can be developed. The strategy will have to be compatible with both the target definition and the protein source. When protein complexes need to be recovered from natural host cells, classical biochemical purification (Deutscher, 1990) appears to be the method of choice when limited information is available on the target, for example, when only its enzymatic activity is known. Biochemical characterization of the complex is then often a tedious process in which various methods such as differential centrifugation, ion exchange chromatography, size exclusion chromatography, or differential precipitation are tested for their ability to enrich fractions of the starting extract for the desired activity while reducing protein complexity (Deutscher, 1990). Combining several

enrichment steps results in the final biochemical purification of the target complex. This strategy has been used to a large extent in the early days of biochemistry and still remains a method of choice. Abundant examples can be found in textbooks with some well-known cases such as the *E. coli* DNA polymerase (Lehman *et al*., 1958; Richardson *et al*., 1964) or the yeast nuclear pore (Rout *et al*., 2000; *see also* Article 41, **Investigating protein–protein interactions in multisubunit proteins: the case of eukaryotic RNA polymerases**, Volume 5).

In theory, any complex should be analyzable following this strategy as long as resources in starting material, time, and money are not limiting. However, this approach suffers from several problems, making its widespread use difficult. The main problem resides in the definition of the purification steps required to recover the complex of interest and their relatively low specificity in the enrichment for the desired target. Selection of the purification steps is often performed by a trial-and-error process, which is tedious and time consuming. Furthermore, the purification efficiency of each step of the procedure is often poor. Thus, many successive steps have often to be combined to result in the recovery of a pure complex. Additional problems may be encountered if the complex is labile. Another complication may arise if the assay used to follow complex purification indicates the presence of the final product of a cascade of reactions. Indeed, the various enzymes will most likely fractionate apart during purification, disrupting the assay even if all activities are intact (e.g., Kramer and Utans, 1991). Two alternatives are then possible: either one has to combine fractions to restore the activity defined in the original assay or one has to define specific assays for each of the partial reactions. It is easy to imagine that inextricable situations may arise if a large number of fractions are required to reconstitute an activity and if, simultaneously, no partial assays are available. Despite these potential pitfalls, biochemical purification is the method of choice to purify a complex when limited information is available on its composition.

In another extreme situation, one may have little information on the activity of a complex but some specific knowledge on its composition. This can be the sequence of one of the protein subunit or an antibody directed against one of its component. It is then tempting to use these data to design an efficient strategy to recover the target complex. If an antibody is available, it can be used in an assay for protein complex purification through the probing of fraction for the presence of the polypeptide of interest (e.g., by western blotting or ELISA) (see Miller *et al*., 2001 for example). However, this reagent can often be used in a more efficient manner as a direct tool for protein purification. In the latter case, antibodies serve as highly specific affinity reagents to fish the target complex out of a crude extract (e.g., Gygi *et al*., 1999). If this immunoaffinity purification strategy is chosen, one has to make sure that relatively large amounts of highly specific antibodies are available. The main advantage of an immunoaffinity procedure is the extremely high and specific enrichment for the target complex that can be achieved in a single step. If the complex is relatively abundant and the antibodies of high quality (e.g., monoclonals), one can even expect in the best cases to visualize the various subunits of the complex on a protein gel after a single purification step. If the target complex is of low abundance, immunoaffinity purification has then to be combined with classical biochemical purification steps. The drawbacks of the method are of various orders. Obviously, the requirement for substantial amount of high quality

antibodies is often limiting. However, the high affinity of antibodies, which make them so efficient for purification, may also become problematic. Indeed, it is often difficult to elute intact complexes from an immunoaffinity column because the harsh conditions required to split the antibody-antigen interaction often induce the simultaneous breaking up of the target complex. This can be avoided, however, when antibodies have been raised against a small peptide that can itself be used as a gentle elution reagent. Nevertheless, if immunoaffinity has to be combined with additional steps during complex purification, it often has to be used last, given the likelihood that the complex will dissociate during elution. Furthermore, one has to consider that the breaking up of the complex after immunoaffinity chromatography may prevent some types of downstream analyses (e.g., activity assays). Obviously, if antibodies are not available but other proteins or chemicals specifically interacting with a subunit of the target complex are known (such as a protein partner produced in large amount as a recombinant factor or an inactive substrate mimic), the latter ones can be used instead for affinity purification.

The efficiency and specificity of affinity purification can also be harnessed if the sequence of a subunit of the target protein complex is known. For this purpose, the sequence coding for a protein domain with defined affinity properties (often called a *tag*) is grafted to the sequence coding for polypeptide of interest through genetic engineering. The corresponding fusion polypeptide, endowed with the binding properties of this new domain, can then be purified efficiently and specifically on the appropriate affinity media (Terpe, 2003). This strategy, which has been extensively used for the expression of single polypeptides, may also be used for protein complexes as long as the other subunits are coexpressed with the tagged one. Thus, if the various subunits of a complex are known, they may all be expressed as recombinant forms (Tan, 2001). However, if only a single subunit of the target complex is known, one has to express the corresponding tagged version in the natural host to allow for complex assembly. The requirement for a host allowing expression of an affinity-tagged protein may thus limit the application of this strategy. The main advantages of affinity tags over antibodies are their constant characteristics. Many tags have thus been developed and one can predict with relatively good accuracy the binding characteristics of the resulting fusion proteins for the corresponding affinity media (Terpe, 2003). Also, gentle elution conditions have been developed for many of them, allowing the recovery of folded proteins or intact complexes rather than denatured partners. Another advantage of tags is the easiness with which one can fuse them to the target protein through standard cloning techniques. A main drawback, however, is the possibility that the tag will interfere with the function and/or the interaction pattern of the fused polypeptide. Despite this problem, tags have proven to be widely useful in the analysis of protein complexes (e.g., Rigaut *et al*., 1999). As for antibodies, tags were found to be sufficient for the recovery of moderately abundant protein complexes in single affinity-purification steps. For low-abundance complexes, strategies using two different affinity tags in a row have been developed (Rigaut *et al*., 1999). In these cases, the two affinity tags could be fused to the same bait protein. Alternatively, two independent baits belonging to the same complex may be each fused to one of the affinity tag (Puig *et al*., 2001; Caspary *et al*., 1999). The latter strategy ensures that the purified material does not contain mostly the free form of an abundant

subunit of a complex of interest. Overall, affinity purification with tags appears as a method of choice for complex purification if the sequence of one subunit of the complex is known and if an appropriate expression system is available.

If all the subunits of a complex are known, the possibility to reconstitute the complex from recombinant subunits is appealing, particularly if large amounts of complexes are required for structural or functional studies. Two opposite strategies are then possible. On the one hand, one can overexpress simultaneously all the subunits in a single system and rely on this system to reassemble the complex (Tan, 2001). On the other hand, each of the subunits may be expressed independently. While this is often technically simpler, suitable conditions allowing the reassembly of the complex in vitro needs then to be developed (e.g., Tan *et al*., 1996). Obviously, a combination of these two strategies may be used when appropriate. Various hosts have been used for the overproduction of recombinant complexes including *E. coli* (Tan, 2001) and baculoviruses (Lawrie *et al*., 2001). The main advantages of the former are the production costs, its rapidity and easy handling, and the wide knowledge accumulated on this host over the years. Furthermore, vectors allowing the coexpression of multisubunit complexes are now available. Baculoviruses are more costly and time consuming but allow for the easy testing of various combinations of coexpressed subunits as those are simply generated by coinfection. In all cases, complexes are often produced at high level and thus necessitate a single (affinity-) purification step before their use. Like for single protein overexpression, recombinant protein complex production may suffer from the potential absence of protein modification and processing that naturally occur in the natural host. However, the main limitation may reside in the number of subunits that this strategy is able to handle, either due to the difficulties associated with overproducing simultaneously many subunits in a single host or because of the problem encountered when reassociating independently produced subunits in vitro. Up to now, only relatively small assemblies have been produced in a recombinant form and larger complexes such as the yeast proteasome (Groll *et al*., 1997) or archeal/bacterial ribosomes (e.g., Wimberly *et al*., 2000) need to be isolated from their natural hosts. However, given the increased interest for protein complexes, one can anticipate that improved strategies for the production of such assemblies will appear in the near future.

5. Biochemical purification of complexes: what for?

Different reasons may lead to the purification of a protein complex. First, one may want to know the partners of a given protein as those may modulate its function or affect its cellular location. The recent developments in mass spectrometry (reviewed by Aebersold and Mann, 2003; *see also* Article 4, **Interpreting tandem mass spectra of peptides**, Volume 5) facilitate this task nowadays by providing a rapid and sensitive manner to identify low amounts of protein. Combined with efficient affinity tags and rapid purification protocols, this technology has allowed large-scale analyses of protein partners in the model eukaryotic species *Saccharomyces cerevisiae* (Gavin *et al*., 2002; Ho *et al*., 2002) as well as in human cells (Bouwmeester *et al*., 2004). These studies have revealed that most

proteins assemble in protein complexes. Data could be compared for yeast for which many large-scale experiments have been performed. Surprisingly, slightly different results were obtained using different tags (von Mering *et al*., 2002) and the data were also poorly overlapping with the pairwise interaction network obtained using the two-hybrid method (Uetz *et al*., 2000). These differences are difficult to explain for the time being. One can expect, however, that accumulating data will attribute these discrepancies to methodological problems and/or difference in the various experiments (strains, growth conditions, etc.). These studies clearly indicate, however, that the functional units of cells are protein complexes rather than independent polypeptides. A second application of the biochemical purification of protein complexes is to learn about the activity and function of an entity once its composition is known. The purified complex may be used in all kinds of biochemical and biophysical assays to get some insights into its biological role. Among them, one may envisage to test for interaction between complexes and/or for posttranslational modifications modulating their activity. Last but not least, a biochemically purified complex of defined composition may be used to get some information on the architectural organization of complexes. This includes simple information on subunit stoichiometry as well as protein–protein contacts and extends to detailed data encompassing the protein complex structure obtained by electron microscopy or X-ray crystallography (Aloy *et al*., 2004; *see also* Article 35, **Structural biology of protein complexes**, Volume 5 and Article 100, **Large complexes and molecular machines by electron microscopy**, Volume 6). Finally, while the list of strategies used to analyze biochemically purified complexes includes a large number of methods, one may anticipate further developments in this area in the near future, given the implication of such assemblies in all cellular functions.

Acknowledgments

Specialist Review

Inferring gene function and biochemical networks from protein interactions

Stephen W. Michnick
Université de Montréal, Montréal, QC, Canada

1. Introduction

The emerging offspring of the genomics revolution variously called proteomics, functional genomics, chemical genetics, or systems biology can be attributed an overall aim: as only a fraction of gene functions can be inferred from primary gene sequences, we need to develop strategies to define gene function that are not conducted at the level of a classical gene-by-gene approach but that aim at characterizing the totality of genes or large subsets thereof. The question then is by what approaches do we meaningfully ascribe function to genes? Furthermore, the emerging fields of systems biology and chemical genetics seek a deeper appreciation of the biochemical organization of living cells and the molecular schemes that all living things share as well as those things that make individual cells and organisms unique. What we seek are conceptual and experimental approaches that will tell us how, when, where, and under what circumstances mRNA message and proteins are processed, become modified to be activated or inactivated, how they are destroyed, and, central to all of these, what other molecules do they interact with.

In this review, I will discuss three issues. First, I will provide some historical, logical, and mechanistic context to explain how the measurement of protein–protein interactions has come to be a crucial component of efforts to define gene function and the organization of biochemical networks. Second, I will explain a conceptual basis for using protein interaction data, along with other approaches such as genome-wide gene expression analysis and genetics to define the organization of biochemical networks. I will specifically discuss how one particular experimental approach, protein fragment complementation assays (PCA), can allow us to go beyond the static representations of protein interactions that we now use, to dynamic studies of protein interactions as a tool for inferring the organization of information flow in biochemical networks. Finally, I will provide some perspectives on where protein interaction networks (PINs) take us, with a discussion of their utility in chemical genetic analyses; the use of organic molecules to both probe biochemical processes and protein interactions as probes for the actions of such molecules on biochemical networks.

2. Protein–protein interactions and gene function

Certainly, an overall goal of genomics is to ascribe function to gene products on a large scale. Even among very well studied organisms such as the budding yeast *Saccharomyces cerevisiae* and enteric bacterium *Escherichia coli*, a significant proportion of their genes cannot be even classified as participating in some general cellular function. Why is this the case and what must be done to remedy the situation for so many genes? It is useful here to take a historical perspective in explaining how techniques have evolved to better address gene function. In the 1980s, there emerged a new breed of biologist, whom we came to call "gene jocks". These were rare individuals who had mastered what were then the new methods of molecular cloning and their utility in identifying the genes underlying biological processes. Specifically, they devised many ingenious strategies to simultaneously screen cDNA libraries using a protein- or enzyme-specific assay that allow for both selection of positive clones and validation of their biological relevance with the same assay (Figure 1a) (see Grimm, 2004 for review) (Aruffo and Seed, 1987; D'Andrea *et al*., 1989; Lin *et al*., 1992; Sako *et al*., 1993). As clever as these screening designs could be, a major barrier to utilizing such approaches on a large scale is that one needs a very specific, sensitive, simple, and scalable assay to directly determine whether a cDNA codes for a sought-after activity. All of this changed following the publication of Fields and Song (1989) on the yeast two-hybrid expression-cloning strategy (Figure 1a). The genius of this approach is that it is a simple, robust and scalable assay, but must important, the detection of interactions of bait proteins of known functions with expressed proteins in a cDNA library is completely general, thus removing the need to develop a specific assay for every gene. The elegance of the two-hybrid expression-cloning approach has made it among the most widely used of techniques and also the first approach used to achieve genome-wide screening for protein:protein interactions in several organisms (Fields and Song, 1989; Drees, 1999; Vidal and Legrain, 1999; Ito *et al*., 2000; Uetz *et al*., 2000; Walhout *et al*., 2000; Ito *et al*., 2001). Completely different, but in vitro strategies to map out protein–protein interactions on a large scale are based on large-scale protein purification followed by mass-spectroscopic analysis (Gavin *et al*., 2002; Ho *et al*., 2002). However, there is a crucial technical distinction between large-scale in vitro approaches versus in vivo techniques such as the two-hybrid system. With in vivo methods, one avoids the complex problem of defining conditions under which proteins can be extracted from cell lysates. For example, extracted proteins may be denatured, exist in a form in the cell that cannot be easily reproduced in vitro, or individual protein complexes may be weakly associated and therefore undetectable in dilute solutions.

A purely protein interaction–based screening approach is limited in that the assays themselves do not provide any immediate information that would allow one to decide whether a cDNA product is likely to be involved in a specific cellular function and so while two-hybrid assays achieve generality, specificity is lost. Ideally, it would be advantageous to combine the generality of two-hybrid screening with the specificity of functional assay-based assays as done in classical expression-cloning approaches. This has been the subject of research in my lab for the last 10 years and, specifically, the development of what we call protein fragment

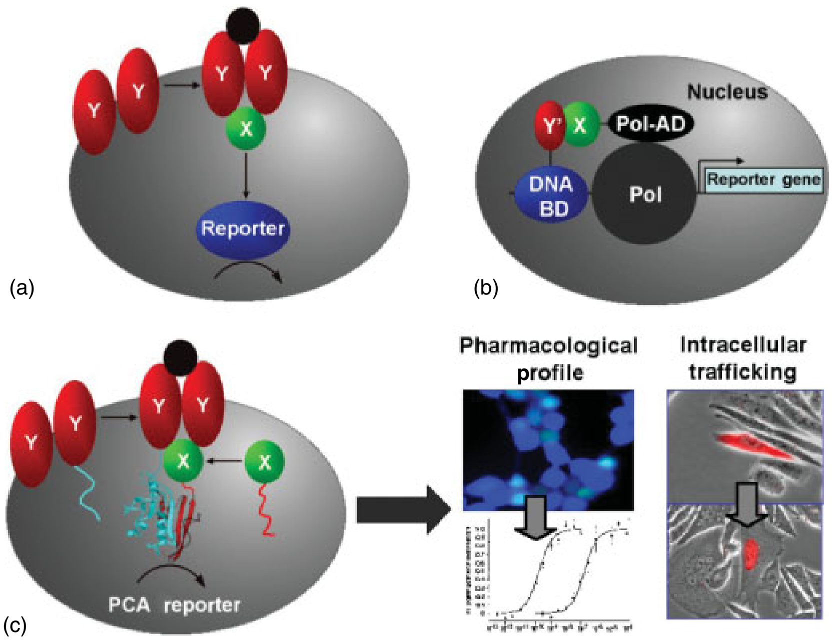

Figure 1 Alternative cell-based expression-cloning strategies. In all examples, a hypothetical intracellular effector protein (X) of a known membrane-associated hormone receptor (Y) is sought by screening a cDNA library. (a) Classical expression cloning strategy. A cell line that expresses receptor Y is transfected with plasmids harboring a cDNA library. An assay is devised to detect whether the potential effector protein cDNA is expressed from a library plasmid, consisting of a reporter enzyme (Reporter), which is activated to produce a detectable product if the receptor is bound to hormone (black sphere). Clonal cells showing reporter activation are isolated and the cDNA-harboring plasmid extracted and sequenced to identify the effector protein X. Note that reporter activation by hormone-induced receptor activation when X is expressed serves as a "first-pass" validation of X being a biologically relevant effector. (b) A yeast two-hybrid expression-cloning strategy. Here it is assumed that effector protein X interacts with an intracellular domain of the receptor Y called Y'. Receptor domain Y' is fused to the DNA binding domain, while a cDNA library is fused to the activation domain of a yeast transcription factor (e.g., Gal4) and expressed in the *S. cerevisiae* nucleus. If plasmid harboring X is expressed simultaneously with Y', the transcription factor is reconstituted, resulting in transcription and expression of a reporter gene (e.g., beta-galactosidase, selectable metabolic marker, etc.). cDNA from positive clones is sequenced to identify putative effector protein X. First-pass validation requires some biological assay (e.g., system described in (a)). (c) A PCA-based expression-cloning strategy. Like the two-hybrid approach, it is assumed that effector protein interacts with the receptor. Unlike the classical approach, no specific assay for receptor activation is required. Receptor Y is expressed as a fusion with one complementary fragment (cyan), while cDNA library is constructed in plasmids as fusion to the complementary fragment (red) of a PCA reporter protein. If X is coded in the cDNA, it interacts with Y, allowing for folding and reconstitution of the PCA reporter protein. (1c, right) First-pass validation is performed by examining response of the interaction of X with Y to hormone stimulation. For example, hormone dose-response of PCA reporter versus or other biologically relevant changes, such as cellular translocation of the X-Y complex (right), are measured

complementation assays (PCA) and their applications to expression cloning. In the general PCA strategy, an enzyme is *rationally* dissected into two fragments and the fragments are fused to two proteins that are thought to bind to each other. Folding of the reporter enzyme from its fragments is catalyzed by the binding of the test proteins to each other, and is detected as reconstitution of enzyme activity (Figure 1c). The PCA strategy takes advantage of the spontaneous all-or-none nature of protein folding and the design of fragments follows from basic concepts of protein engineering. The all-or-none folding of reporter protein from fragments means that the generation of signal by complementation has an enormous dynamic range over a very narrow range conditions, unlike fluorescence resonance energy transfer techniques (Zhang *et al*., 2002). We demonstrated the principle of PCA and it has been generalized to a number of enzymes including dihydrofolate reductase, glycinamide ribonucleotide transformylase, aminoglycoside kinase, hygromycin B kinase, TEM ß-lactamase, green fluorescent protein (GFP), and firefly and renilla luciferases (Pelletier *et al*., 1998; Pelletier *et al*., 1999; Remy *et al*., 1999; Ghosh *et al*., 2000; Michnick *et al*., 2000; Remy and Michnick, 2001; Remy *et al*., 2001; Galarneau *et al*., 2002; Hu *et al*., 2002; Paulmurugan *et al*., 2002; Spotts *et al*., 2002; Wehrman *et al*., 2002; Paulmurugan and Gambhir, 2003). The application of PCAs to library screening has been demonstrated in a systematic model and to screening of cDNA libraries. The cDNA library screening strategy consists of two steps (Figure 1c): First, a large-scale screening of “bait” proteins (X) fused to one PCA reporter fragment against a cDNA library fused to the complementary reporter fragment. In the second step, positive hits from the screen are then directly functionally “validated” by testing for perturbations of the interaction, as measured by PCA, by agents that act on the biochemical network in which the bait protein is known to participate. We have described a cDNA library screening strategy using a GFP-based PCA in which we successfully identified novel substrates and regulators of the serine/threonine protein kinase PKB/Akt (Remy and Michnick, 2004a; Remy *et al*., 2004).

The PCA strategy has these unique features:

- Molecular interactions, including complete cellular networks, are detected directly – not through secondary events such as transcription activation.
- Genes are expressed in the relevant cellular context, reflecting the native state of the protein, with the correct posttranslational modifications.
- Events induced by hormones or growth factors can be detected, providing target validation by linking specific interactions to specific networks. For example, using insulin-sensitive cells, molecular interactions stimulated by insulin can be detected and quantitated.
- The subcellular location of protein interactions can be determined, whether in the membrane, cytoplasm, or nucleus and the movement of protein complexes can be visualized.

In addition to the specific capabilities of PCA described above, are special features of this approach that make it appropriate for genomic screening of molecular interactions, including: (1) PCAs are not a single assay but a series of assays; an assay can be chosen because it works in a specific cell type appropriate

for studying interactions of some class of proteins; (2) PCAs are inexpensive, requiring no specialized reagents beyond those necessary for a particular assay and off-the-shelf materials and technology; (3) PCAs can be automated and high-throughput screening could be done; (4) PCAs are designed at the level of the atomic structure of the enzymes used; because of this, there is additional flexibility in designing the probe fragments to control the sensitivity and stringencies of the assays; (5) PCAs can be based on enzymes for which the detection of protein–protein interactions can be determined differently including by dominant selection or production of a fluorescent or colored product.

3. Mapping the biochemical machinery of cells

The potential application of genome-wide approaches to cellular biology is becoming a reality. For example, drawing upon systematic genome-wide analyses of *S. cerevisiae*, several groups have suggested that biochemical networks may be organized as modules of physically or genetically linked genes that contribute to a particular cellular function (Hartwell *et al*., 1999; Winzeler *et al*., 1999; Ihmels *et al*., 2002; Snel *et al*., 2002; Rives and Galitski, 2003; Tong *et al*., 2004; Yao *et al*., 2004; Yook *et al*., 2004), and it has been proposed that such analyses could be used to identify cellular processes to which specific genes are linked and upon which cellular perturbations act (Hartwell *et al*., 1997; Marton *et al*., 1998; Giaever *et al*., 1999; Hardwick *et al*., 1999; Hughes *et al*., 2000; Kuruvilla *et al*., 2002; Giaever *et al*., 2004; Lum *et al*., 2004; Parsons *et al*., 2004).

Why is it that the systematic collection of protein–protein interactions is so important to the goal of delineating the biochemical networks that underlie cellular processes? The reason is a fundamental fact about the nature of biochemical networks. Biochemical processes are mediated by dynamic noncovalently associated multienzyme complexes that permit the most efficient chemical machinery, in which the substrates and products of a series of steps are transferred from one active site to another over minimal distance, with minimal diffusional loss of unstable intermediates, and in chemical environments suited to stabilizing reactive intermediates (Perham, 1975; Pawson and Nash, 2000; Vidal, 2001). Biochemical "networks" are complexes of dynamically assembling and disassembling protein complexes and, therefore, a meaningful representation of a biochemical network in a living cell would be first, a step-by-step analysis of individual protein–protein interactions and second, analysis of the dynamics of interactions in response to perturbations that impinge upon the network under study and the temporal and spatial distribution of these interactions.

How can protein interaction networks (henceforth, PINs) help us to study these dynamic assembly events? It is first instructive to examine how biochemical networks have been studied at a genome-wide scale in gene transcription experiments. The advent of DNA microarray technologies has changed the manner in which we view biochemical networks (Chu *et al*., 1998; Holstege *et al*., 1998; Spellman *et al*., 1998; Hughes *et al*., 2000; Roberts *et al*., 2000; Ideker *et al*., 2001). A strategy for mapping biochemical networks on the basis of expression profiles depends on two components: first, the ability to monitor the expression

of genes on a genome-wide level and second, ways to systematically perturb the biochemical networks underlying the expression of genes in a systematic way (Figure 2). The key practical issue is whether a set of specific perturbations is possible. In yeast, this is relatively simple thanks to the availability of a systematic set of gene knockouts, while for other organisms, siRNAs are coming to be the most common approach to gene perturbation (McManus and Sharp, 2002). The practical monitoring of changes in expression of complete genomes or large subsets of genes has allowed researchers to begin to scrutinize in some detail the evolution of genetic programs and sometimes, by inference, the underlying biochemical networks that control these programs. The most well described analyses of gene expression have been performed for the bakers yeast *S. cerevisiae*, for which the entire genome

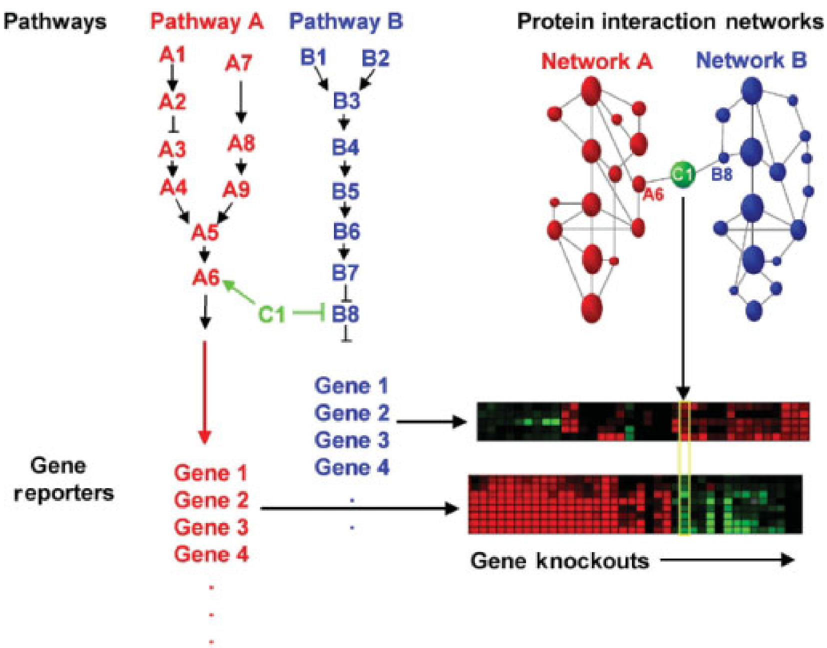

Figure 2 Combining gene expression profiles and protein-interaction networks to determine the organization of biochemical pathways. Two related pathways (A and B) are thought to be organized as depicted (upper left). The role of each protein as an activator (arrows) or inhibitor (T-bars) of the pathway is indicated. Interactions of the component proteins of these pathways (upper right) suggest a modular organization in which an additional protein (C1) has been identified, linking the two pathways. In order to confirm the organization of these pathways and role of each protein, the expression of reporter genes that are activated by the individual pathways are monitored (lower right). Relative expression levels are determined for wild-type versus cells in which individual pathway component proteins have been knocked out. The position in the pathway and role of the novel pathway integrator C1 are determined. First, the position of C1 in the pathways is determined by which proteins in the two pathways C1 interact with (A6 and B8). Second, the role of C1 is determined by comparing reporter gene expression in wild-type and cells in which C1 is knocked out (lower right, yellow rectangle). Knocking out C1 results in an increase in expression of pathway B reporter genes (red squares) and a decrease in expression of pathway A reporter genes (green squares). Expression profile results are consistent with an inhibitory role of C1 on pathway B and an activating role on pathway A as depicted

has been sequenced and microarrays representing all predicted genes have been available for some time (Lashkari *et al*., 1997). Complete analyses of the cell cycle and responses of the organism to a number of perturbations have been explored. It is possible to conceive of mapping the output of a genetic program (gene expression changes) back to the organization of the biochemical networks underlying these changes. This transcriptocentric approach to mapping networks does not help us to side-step an obvious problem: If you do not know the details of the underlying machinery leading to specific outputs of a system, then any new insights from analyzing outputs remain inferences that must still be tested directly. It is like saying that you might be able to figure out how a radio works by monitoring the audio output and systematically removing components while changing the tuning and other settings. This is where PINs become an important component of a more detailed analysis of biochemical networks. PINs have already been used extensively as a strategy to identify genes involved in a wide range of biological processes from the development of specific organs to the identification of pathogenic proteins (Walhout *et al*., 2000; Rain *et al*., 2001). However, it was Ideker and colleagues who first described how a PIN can be used to guide a systematic analysis of a biochemical network, using a unique metabolic response, the switch from glucose to galactose as carbon source in yeast as an example (Ideker *et al*., 2001). In their strategy, a PIN is constructed for all known interactions for proteins, which are either known to interact or might be inferred to interact on the basis of common changes in expression in response to the glucose-galactose switch. Combining these data with examinations of changes in protein expression and knockouts of individual genes, they were able to both reproduce what was known about the glucose-galactose response, and to identify some proteins whose role in the response was not known. Thus, the PIN constructed for the glucose-galactose response genes served as a template for generating and testing hypotheses about the organization of a biochemical network underlying a simple but important biological adaptation. Another elegant example of where a PIN was used as the framework for the detailed analysis of the biochemical networks underlying a process was done by Yao and colleagues on how proteins involved in the vertebrate aryl receptor response could be organized into functional classes of interacting components (Yao *et al*., 2004).

In the examples described above, PINs are static entities; that is, they reflect simply existing knowledge from a variety of sources of which proteins interact with each other. It would be of tremendous value if the interactions themselves could be studied as dynamic entities. Specifically, if we could understand where, when, and how interactions are occurring in a living cell, we could use these sources of information not merely as a framework for constructing a static map of biochemical networks but a dynamic description of information flow through networks.

In a PCA-based biochemical network mapping project, specific PCAs for proteins that interact at various strategic points (for example at different points in a pathway hierarchy) in a network serve as "sentinels" for the state of the pathway under different conditions. First, cells containing PCA sentinels are treated with agents (chemical inhibitors siRNAs, hormones, etc.) that would be thought to perturb the biochemical network under study. A change in the PCA sentinels reporter signal would then reveal that the relationship is between the point of action of

the perturbing agent (say, some enzyme in a subnetwork or "module") and the sentinels. So for instance, if an enzyme were inhibited with a small molecule and the sentinel signal decreased, we could hypothesize that this enzyme must be somehow positively coupled to the function of the sentinel proteins. A series of perturbations within individual modules in the network would result in a pattern of responses or "pharmacological profile", as detected by PCA, which should be consistent with the response of the pathway under study. Second, interactions of protein components of a network should take place in specific subcellular compartments or locations consistent with the function of the network. The combined pharmacological profiles and subcellular interaction patterns serve then to describe a biochemical network (Remy and Michnick, 2001; Remy and Michnick, 2004b,c; Remy *et al*., 2004).

As much as we want to know how the components of biochemical networks interact with each other, we also want to know how agents (e.g., siRNAs, gene knockouts, small organic molecules) that perturb these networks exert their effects. For example, even if we know that a small organic molecule acts very specifically on some target protein in vitro, this in no way assures that the consequences of the actions of the molecule on the target in the cell can be predicted. Three examples illustrate how this PCA sentinel approach might be applied to determine actions of a small molecule on the cell. In a first example, a small molecule has been shown to act on a specific target. We thus verify the predicted outcome on the network in which the target protein participates, by testing the compound against a series of PCA sentinels that report on the state of that network and also on a series of control networks. If the molecule does what we predict, only the target network is affected, however, if sentinels in other networks report perturbations, then the specificity of action of the molecule must be reevaluated. In a second example, a novel compound has been shown to cause some profound phenotype in a cell and we want to quickly link the observed phenotype to effects on known networks that would likely be those affected. The same strategy is used as above, but in this case we hypothesize that in order to obtain the observed pleiotropic phenotype, more than one network must be affected. A third example is one in which the specific target of a compound is known, but paradoxically, predicted effects on cell do not occur because of feed back from a branch in the biochemical network that compensates for the inhibition of a target. There are numerous examples of such paradoxes (Hall-Jackson *et al*., 1999). In these cases, a "two-hit" strategy of knocking out both the target and another target in the compensating branch (as monitored by the PCA sentinels signals) might produce a profound phenotype in the cell, while hitting either individual target would do nothing.

The strategies described above turn chemical genetics to a new focus that we call "network-based targeting", as opposed to protein targeting that is usually practiced. There are some considerable advantages of network targeting that can be summarized as follows: (1) optimal target(s) for a network of interest can be identified in simple cell-based assay; (2) the evaluation of off-pathway effects can be studied with the same assays; (3) the assays are simple and performed in intact cells and thus necessitate neither the production of recombinant proteins nor protein purification, as is required for the development of large scale in vitro based assays, often an intractable problem; (4) finally, this strategy enables the analysis of combinations of perturbations that may impact multiple targets simultaneously.

4. Conclusions and perspectives

I have attempted here to provide an overview of how the construction of PINs can and will continue to guide efforts to provide the basis for gene function assignment and for studying biochemical networks. Static PINs as provided by two-hybrid and mass-spectroscopic approaches will have an enduring place in these efforts, while PCA-based approaches will allow us to "place" each gene product at its relevant point in a network and define the dynamic organization of the network. Specific chemical and other perturbations could be used to generate a functional profile, including dominant-negative forms of enzymes, receptor- or enzyme-specific peptides, or siRNAs. The ability to monitor the network in living cells containing all of the components of the network studied can reveal hidden connections and will allow for a full investigation of the global organization of biochemical networks in cells and to address fundamental questions about how biochemical machineries are organized (Hartwell *et al*., 1999). Finally, I discussed how network mapping could be used in combination with other genome-wide approaches to increase the quantity and quality of information about the actions of small molecules on the living cells and the intricate networks that make up their chemical machinery.

Specialist Review

The *C. elegans* interactome project

David E. Hill, Michael E. Cusick and Marc Vidal
Dana-Farber Cancer Institute, Harvard Medical School, Center for Cancer Systems Biology, Boston, MA, USA

1. Introduction

Molecular biology has uncovered fundamental mechanisms of biology and of human disease, but essential questions remain unanswered. Particularly, since gene products usually mediate their function in association with other gene products, biological processes need to be regarded as complex cellular networks of interconnected components. It is increasingly apparent that such complex networks have properties of their own, sometimes referred to as "emergent properties". Those properties might relate back to intriguing novel biological phenomena (*see* Article 118, **Data collection and analysis in systems biology**, Volume 6).

Thus, to understand both normal biological processes of interest as well as molecular disease mechanisms, one needs to consider systems approaches that allow global analyses of the properties, dynamics, and functions of the molecular networks in which gene products act (Ideker *et al*., 2001; Vidal, 2001). It is becoming clear that even when we will have precise structural and functional information on most gene products, we still will not be able to fully understand biological phenomena and disease mechanisms. Again, this is because the systems formed by large numbers of individual genes, proteins, RNAs, and metabolites tend to exhibit properties that are not observable by reductionism, which consists in studying genes one at a time. Such a paradigm shift is particularly important to consider in light of novel therapeutic strategies. For a thorough understanding of drug action, and to maximize our chances of finding novel robust therapies, we probably will need to pay more attention to the complexity of cellular networks (Kitano, 2002).

One of the first steps in the development of global approaches to comprehend molecular networks is the systematic mapping of macromolecular interactions and biochemical reactions. Since many gene products mediate their function or are regulated through physical protein–protein interactions, we need to develop ways to comprehensively map protein–protein interaction, or "interactome", networks (*see* Article 39, **The yeast interactome**, Volume 5). Ultimately, our goal should be to generate a high-quality "human interactome map" that, together with other functional genomic and proteomic (or "omic") information, will serve as a backbone

for the drawing of global functional wiring diagrams (Vidal, 2001; Ge *et al*., 2003). Given how the human genome project (HGP) (*see* Article 24, **The Human Genome Project**, Volume 3) benefited from the sequencing and annotation of the genome of various model organisms, it was proposed several years back that the launching of a human interactome project would also require the development of interactome projects for the proteome of selected model organisms (Walhout *et al*., 1998).

Using the nematode *Caenorhabditis elegans* as a model system, we have developed several key solutions to the challenges inherent to the making of interactome maps for metazoan organisms. So far, we have generated a *C. elegans* interactome map that contains ∼5500 potential interactions, referred to below as Worm Interactome Version 5 (WI5) (Walhout *et al*., 2000b; Davy *et al*., 2001; Matthews *et al*., 2001; Boulton *et al*., 2002; Walhout *et al*., 2002; Reboul *et al*., 2003; Li *et al*., 2004; Tewari *et al*., 2004). This dataset, together with a recently released interactome map for *Drosophila melanogaster*, represents the first interactome map for metazoan organisms.

Although already helpful, the protein interaction data in WI5 is far from complete and needs improvements. We will discuss how to improve interactome maps on three fundamental aspects of the worm interactome map: completeness, sensitivity, and specificity.

2. Yeast interactome maps

The yeast *Saccharromyces cerevisiae* has been used to develop "unicellular" eukaryotic interactome maps (*see* Article 39, **The yeast interactome**, Volume 5). Large-scale proteome-wide experiments, including high-throughput yeast two-hybrid (HT-Y2H) screens (Uetz *et al*., 2000; Ito *et al*., 2001), affinity purifications followed by mass spectrometry (AP-MS) (Gavin *et al*., 2002; Ho *et al*., 2002), and computational predictions (Dandekar *et al*., 1998; Marcotte *et al*., 1999; Pellegrini *et al*., 1999), together with interactions collected in the MIPS database (Mewes *et al*., 2002; *see also* Article 45, **Computational methods for the prediction of protein interaction partners**, Volume 5) have provided ∼28 000 protein–protein interactions, 2493 of which were identified by at least two of these four sources (constituting the basis of a "filtered yeast interactome" or FYI dataset (Han *et al*., 2004)).

These yeast interactome maps have provided hypothetical functions for hundreds of uncharacterized genes by following the "guilt-by-association" approach, whereby proteins that have similar biological functions tend to cluster together in interactome networks (Schwikowski *et al*., 2000; *see also* Article 46, **Functional classification of proteins based on protein interaction data**, Volume 5). Although the map for the yeast interactome network is far from complete and could be improved in sensitivity and specificity (Grigoriev, 2003), some of its "emergent" global topological properties have already become evident. For example, the yeast interactome network is scale-free, that is, most proteins interact with few partners, while few proteins, the "hubs", interact with many partners (Jeong *et al*., 2001). The small-world nature of protein networks also allows inference of some protein interactions from others (Goldberg and Roth, 2003). Finally, the yeast interactome

data correlate significantly with other functional genomic approaches such as expression (transcriptome) and phenotypic (phenome) profiling (Ge *et al.*, 2001; Grigoriev, 2001; Begley *et al.*, 2002; Jansen *et al.*, 2002; Kemmeren *et al.*, 2002), suggesting that a global understanding of the yeast proteome might arise from the integration of several systematic "-omic" approaches (Vidal, 2001; Ge *et al.*, 2003).

3. *C. elegans* as a model "-omic" organism

Caenorhabditis elegans is a useful multicellular model organism because: (1) genetic manipulations are efficient (Riddle *et al.*, 1997), (2) transgenic animals are conveniently generated (Praitis *et al.*, 2001), (3) its cellular lineage is invariant (all cells are named) and has been more extensively studied than in any other organism (Sulston and Horvitz, 1977; Sulston *et al.*, 1983), (4) its genome is completely sequenced (The C. elegans Sequencing Consortium, 1998), and (5) there is often functional conservation between worm genes and their human orthologs (Pennisi, 1998; Walhout *et al.*, 1998; Tewari *et al.*, 2004). Hence, many biological models obtained from studying the worm can be directly used to predict gene and network functions in human molecular networks. Examples include the discovery of the Ras pathway (Sternberg and Han, 1998; Walhout *et al.*, 2000b), and the discovery of programmed cell death in *C. elegans,* especially the roles of the worm orthologs of caspase (CED-3) and Bcl2 (CED-9) (Yuan and Horvitz, 1990; Hengartner and Horvitz, 1994; Yuan and Horvitz, 2004).

The *C. elegans* EST project has identified more than 12 000 expressed genes to date (Hanazawa *et al.*, 2001). In addition, we initiated genome-wide experimental tests to address the quality of both the gene number estimate and the predictions of exon structure (Reboul *et al.*, 2001; Reboul *et al.*, 2003; Lamesch *et al.*, 2004). Finally, the genomic information is freely available on a widely used database, Wormbase (**http://www.wormbase.org**), in which the genetic data, the physical maps, the genome sequence, and the EST sequences are stored and organized in a user-friendly manner (Stein *et al.*, 2001).

Several laboratories have initiated large-scale projects aimed at describing loss-of-function phenotypes for every single predicted *C. elegans* open reading frame (ORF) using RNAi technologies (Fraser *et al.*, 2000; Gonczy *et al.*, 2000; Piano *et al.*, 2000; Maeda *et al.*, 2001; Kamath *et al.*, 2003; Rual *et al.*, 2004a). A gene expression map, or "topomap", has been deduced from DNA microarray experiments involving ~17 000 genes across more than 550 different conditions (Kim *et al.*, 2001). New technologies are also being developed to solve the 3D structure of many *C. elegans* proteins (Chance *et al.*, 2002; Luan *et al.*, 2004). Additionally, the "localizome" project is under way to determine in what cell and at what stage of development each ORF is expressed (Hope *et al.*, 1996; Dupuy *et al.*, 2004). Finally, an HT-Y2H protein interaction mapping project is ongoing in our laboratory (Walhout *et al.*, 2000b; Davy *et al.*, 2001; Boulton *et al.*, 2002; Walhout *et al.*, 2002; Reboul *et al.*, 2003; Li *et al.*, 2004; Tewari *et al.*, 2004). Importantly, we are in the process of learning how to integrate such large-scale high-throughput datasets with other types of functional genomics data (Boulton *et al.*, 2002; Walhout *et al.*, 2002).

4. Gateway cloning of ORFeomes for functional proteomics

An important challenge in the development of systems approaches is to be able to express nearly all predicted proteins identified as potentially implicated in a biological process of interest, under different conditions and in various hosts. This in turn allows the development of various large-scale functional genomic and proteomic approaches. For example, HT-Y2H (Walhout *et al*., 2000c) and AP-MS (Gavin *et al*., 2002; Ho *et al*., 2002) strategies, as well as proteome chips or reverse transfection strategies (Zhu *et al*., 2001; Ziauddin and Sabatini, 2001), require large numbers of protein-encoding ORFs to be cloned precisely into multiple expression vectors.

Randomly picked cDNA clones in the context of various "transcriptome" projects can rarely be used directly for protein expression, because either their 5′-end is not cloned in the appropriate reading frame, or their 3′-end is not compatible with the expression of C-terminal fusion proteins, or both. Additionally, most cDNAs produced in transcriptome projects are *not* available in vectors that allow transfer of the protein-encoding sequences to a variety of expression vectors by automated, high-throughput methods. Furthermore, standard methods of adding suitable restriction sites to the ends of either DNA fragments or PCR products and then employing restriction digestions and ligations to subclone desired DNA fragments are not readily compatible with high-throughput systems.

To address these problems, an alternative strategy, Gateway recombinational cloning, for manipulating DNA from any source for primary or secondary cloning purposes and utilizing in vitro reactions amenable to high-throughput settings was developed several years ago (Hartley *et al*., 2000; Walhout *et al*., 2000c). Gateway bypasses the need for traditional enzymatic digestion, purification, and ligation of DNA molecules, and is particularly suited for cloning large numbers of DNA fragments, such as ORFs. The Gateway systems employs a two-step strategy, whereby the initial step is the generation of "Entry clones", which constitute a standardized resource that can be shared with the scientific community. Any DNA, such as ORFs, obtained as an "Entry clone" can then subsequently be transferred to any Gateway-compatible expression vector, termed a *Destination clone*, without reducing the quality of the original resource, and virtually any standard expression vector is readily modified into a Destination Vector by inserting a 1.8-kb cassette that contains all the necessary Gateway sequences (Hartley *et al*., 2000; Walhout *et al*., 2000c). The power of the Gateway cloning system is that a collection of ORFs "stored" as Gateway Entry clones can be transferred in parallel to one or more Destination Vectors in a simple in vitro reaction that can take place in 96-well or 384-well plates.

5. The *C. elegans* ORFeome project

We implemented this Gateway cloning to generate a collection of cloned ORFs for further functional genomics and proteomics studies (Reboul *et al*., 2001; Reboul *et al*., 2003; Rual *et al*., (2004b)). The model system chosen was the nematode *C. elegans* because of the relative simplicity of its genome (e.g., small introns and

short intergenic sequences) and the high quality of its genome sequence (The *C. elegans* Sequencing Consortium, 1998). On the basis of gene annotations and gene prediction tools, the *C. elegans* genome is expected to contain >19 000 protein-encoding genes. PCR reactions were performed with 19 477 pairs of Gateway-tailed ORF-specific primers using as templates a highly representative cDNA library generated from all stages of *C. elegans* development (Walhout *et al*., 2000b).

After Gateway cloning, the resulting PCR products into the Donor vector pDONR201, pools of transformants for each ORF Entry clone were subjected to ORF sequence tags (OSTs) analysis to verify both gene identity and the presence of at least one splicing event. Such ORF pooling strategy allows the maintenance of a diversity of splice variants in each Entry clone (i.e., between the Start and Stop primers) while providing experimental verification of exon–intron structure for each cloned ORF. In addition, the pooling strategy facilitated the throughput needed for the completion of the project. All ~12 000 successfully cloned and sequenced ORFs were then rearrayed to generate "version 1.1" of the *C. elegans* ORFeome (Reboul *et al*., 2003) with pertinent data on each cloned ORF available via a searchable website at **http://worfdb.dfci.harvard.edu** (Vaglio *et al*., 2003).

6. Genome annotation and ORFeome resources

Genome annotation is still a very dynamic process, as more experimental data is obtained to verify both gene structure and expression. The *C. elegans* community has actively maintained a database that regularly updates the gene annotation (Stein *et al*., 2001). Originally, version 1.1 of the *C. elegans* ORFeome was obtained using the August 1999 WormBase genome annotation version WS9, in which ~50% of ORFs were accurately predicted, leaving over one-half of all ORFs needing improved annotation (Reboul *et al*., 2003). One consequence of this was that a significant fraction of the ORFs could not be amplified owing to mispredictions leading to erroneous primer design (Reboul *et al*., 2001; Reboul *et al*., 2003). Recently, we utilized an updated version, WS100 (May 2003), to redesign primers for 3000 newly predicted or repredicted ORFs, and obtained ~2000 of these corrected ORFs. Through this iterative process, we now have ~13 000 ORFs in ORFeome, Version "3.1" which includes the 11 000 original cloned ORFs plus 2000 corrected or newly predicted ORFs (Lamesch *et al*., 2004). As the *C. elegans* genome annotations keep improving, for example, from the comparison with the genome sequence of related nematodes such as *C. briggsae* (Stein *et al*., 2003), better ORFeomes will become available and, consequently, we will approach a finishing point of our ORFeome resource.

Gateway cloning of ORFs is not restricted to eukaryotic cDNAs. Bacterial genomes are also amenable to using Gateway for generating ORFeome collections. However, while exon–intron structure is not an issue for bacterial genomes, there are still significant challenges in gene prediction, namely, in the start site for individual ORFs. For example, construction of a *Brucella melitensis* ORFeome required manual curation to identify and correct the start site of translation for over one-quarter of the 3198 predicted ORFs (Dricot *et al*., 2004). On the basis of both gene prediction tools and manual curation, an ORFeome cloning project

using Gateway was able to obtain 3091 ORFs from this organism (Dricot *et al*., 2004).

7. Improved yeast two-hybrid for large-scale protein interaction mapping

With the availability of Gateway-cloned *C. elegans* ORFs, we have carried out protein–protein interaction mapping studies using a highly reliable, high-throughput yeast two-hybrid (HT-Y2H) system (Walhout *et al*., 2000a; Walhout and Vidal, 2001). The canonical and most commonly employed Y2H system is based on the reconstitution of a transcription factor (e.g., Gal4) (Fields and Song, 1989). DNA sequences coding for proteins of interest X and Y are separately fused to sequences coding for the Gal4 DNA binding (DB) and activation domains (AD), respectively, to create sequences coding for "DB-X" and "AD-Y" hybrid proteins. HT-Y2H screening has been widely used for protein interaction mapping because it manipulates DNA not proteins, making it amenable to both standardization and high throughput.

Earlier versions of the Y2H were inconsistent because they displayed (1) high numbers of false-positives, thereby generating a high background, (2) no direct link between physical interaction and function, and (3) limited automation. In response to these issues, an improved version of the Y2H that significantly lowers the rate of false-positives and is amenable to automation has been developed (Vidal, 1997; Walhout and Vidal, 2001; Vidalain *et al*., 2004) and utilized for our worm protein–protein interaction, or "interactome", mapping project (Li *et al*., 2004).

8. The *C. elegans* interactome project: modular screens

Our *C. elegans* interactome map started with medium-throughput Y2H interactome maps generated for distinct biological processes, or "modules": vulval development, protein degradation, DNA damage response, germ-line formation, and dauer formation (Walhout *et al*., 2000c; Davy *et al*., 2001; Boulton *et al*., 2002; Walhout *et al*., 2002; Tewari *et al*., 2004). Our first attempt at interactome mapping involved the orthologs of the pRb and Ras pathways in the worm, both pathways critical for vulval development (Walhout *et al*., 2000c). To generate this map, ~30 ORFs were fused to DB and used to screen a worm AD-cDNA library (Walhout *et al*., 2000c). Approximately 150 potential interactions were identified involving 18 characterized (and named) genes and ~100 uncharacterized ORFs. More than 50% of interactions previously reported in the Ras and pRb pathways were found, and interesting patterns were observed, including clusters of interactions involving interactions conserved in other species ("interologs") and potential global networks of interactions. This analysis contributed to the understanding of Ras and pRb pathways in *C. elegans* as well as in human. Subsequent modular maps examined the 26 S proteasome complex (Davy *et al*., 2001), proteins implicated in the DNA damage response (DDR) and cell-cycle checkpoint (Boulton *et al*., 2002), proteins

suspected to function in the development of the *C. elegans* germline (Walhout *et al*., 2002), and proteins known to function during larval stages in response to environmental stress that results in a development arrest decision leading to dauer formation instead of normal hermaphrodite adults (Tewari *et al*., 2004). These module-scale networks were shown to (1) contain valuable information to formulate biological hypotheses for large numbers of uncharacterized proteins, (2) provide new potential links between proteins already known to be involved in certain biological processes, and (3) point to unexpected functional relationships between seemingly distinct biological processes (*see* Article 46, **Functional classification of proteins based on protein interaction data**, Volume 5).

9. The *C. elegans* interactome project: multicellularity and large-scale screens

To investigate the fraction of the worm interactome most likely important to multicellularity, we selected a set of ~3000 predicted proteins as Y2H baits, on the basis of structural and functional criteria that relate to multicellularity (Li *et al*., 2004). The proteins selected for this analysis were grouped in three classes: ~350 proteins with a clear ortholog in unicellular yeast ("Ancient"), 2200 proteins with a clear ortholog in multicellular organisms including *Drosophila*, *Arabidopsis*, or humans but not in yeast ("Multicellular"), and 400 proteins with no obvious ortholog outside of *C. elegans* ("Worm"). Out of these ~3000 selected baits, ~2000 were present in the ORFeome version 1.1. Of these, a few autoactivated the Y2H *GAL1::HIS3* reporter gene as DNA binding fusion baits (DB-X), or conferred toxicity to yeast cells, and so were eliminated from the population of baits used for subsequent Y2H analysis.

The remaining DB-X baits were screened against two different Gal4 activation domain (AD-Y) libraries, each with distinct yet complementary advantages. The AD-ORFeome 1.0 library (generated by pooling all ~11 000 cloned ORFs from the ORFeome resource (Reboul *et al*., 2001; Reboul *et al*., 2003)) is normalized (each ORF present in equal abundance) but is limited because many biologically relevant protein–protein interactions cannot be detected by Y2H assay when strictly using full-length proteins (Legrain and Selig, 2000; Uetz *et al*., 2000). In contrast, AD-wrmcDNA (Walhout *et al*., 2000b) is *not* normalized, but it contains multiple alternative AD-Y junction sequences for most genes, and so encodes multiple domain arrangements for each protein represented. The combined AD-ORFeome 1.0 and AD-wrmcDNA libraries contain an estimated 14 000 AD-Y fusions (collapsing splice variants into single genes) (Reboul *et al*., 2003).

Specificity of the Y2H can be maximized by applying stringent experimental and bioinformatics criteria (Vidalain *et al*., 2004). First, three different Gal4-responsive promoters are used to minimize nonspecific promoter activation (Vidal, 1997) and AD-Y clones are only considered if they activate at least two of the three promoters. Second, expressing both DB-X and AD-Y from single-copy, not multicopy, plasmids reduces spurious effects due to overexpression of bait and/or prey. Third, all interaction pairs are retested in fresh yeast cells to eliminate

spontaneously arising auto-activators and to confirm the reproducibility of the interaction. Finally, Y2H interactor-encoding cDNAs or ORFs are PCR-amplified directly from yeast colonies and sequenced, giving rise to Interaction Sequence Tags (ISTs) (Walhout *et al*., 2000b). For each IST, the AD-Y reading frame is verified to avoid recovering out-of-frame peptides. For the *C. elegans* Interactome (Li *et al*., 2004), employing ∼2000 baits, ∼16 000 ISTs were initially obtained. The interactions between bait and prey were then subdivided into three confidence classes: those found at least three times independently and for which at least one IST revealed an in-frame AD-Y junction (Subset "Core-1"); those found fewer than three times but passed the retest and for which at least one IST revealed an in-frame AD-Y junction (Subset "Core-2"); and all other Y2H interactions found in our screens (Subset "Non-Core"). By these criteria, and combined with the interactions found in our modular screens and through interologs, the current interactome map is a network of 5500 high-quality interactions (Li *et al*., 2004).

10. Properties of the *C. elegans* interactome network

The current *S. cerevisiae* interactome is a scale-free network, a topology that might relate to genetic robustness (Jeong *et al*., 2001; Gu *et al*., 2003). We used the WI5 Core dataset to investigate the topology of the *C. elegans* interactome. As bait proteins have more interactors than prey proteins on average, the analysis on degree distribution should be conducted separately for bait and prey proteins to avoid bias. When the proportion of *C. elegans* proteins that have k interactors ($P(k)$) is plotted against k on a log–log scale, a linear curve is obtained, similar to that seen for *S. cerevisiae* (Li *et al*., 2004). Thus, the worm interactome also exhibits a "scale-free", or power law, degree distribution. In addition, the worm interactome network exhibits small-world properties. These observations extend previous findings that many other biological networks also exhibit small-world and scale-free properties (Wagner, 2001; *see also* Article 27, **Noncoding RNAs in mammals**, Volume 3).

This WI5 Y2H dataset also allows us to analyze whether or not evolutionary recent proteins tend to preferentially interact with each other rather than with ancient proteins. Subdividing the nodes of the network into "ancient", "multicellular", and "worm" proteins as defined above, the three groups seem to connect equally well with each other, suggesting that new cellular functions rely on a combination of both evolutionary new and ancient components (Li *et al*., 2004; *see also* Article 37, **Functional analysis of genes**, Volume 3).

11. Accuracy of the *C. elegans* interactome map

ISTs identified in any Y2H study can arise due to the nature of Y2H itself rather than a bona fide interaction between two polypeptides. These "biological false-positives" can appear to be real-positives after retesting in yeast but are shown to be false-positives when tested in an entirely different assay system. Thus, even with stringent criteria for identifying putative interacting proteins via

Y2H, it is better to experimentally assess the overall quality of Y2H results in an alternative assay. To experimentally assess the overall quality of our HT-Y2H scheme, a representative sample of interaction pairs from each of the three datasets, Core-1, Core-2, and Non-Core, was tested in an in vivo coaffinity purification (co-AP) Glutathione-S-Transferase (GST) pull-down assay. Interactions detected in a completely different protein interaction assay are unlikely to be technical false-positives. ORF pairs corresponding to Y2H interactions were retrieved from our ORFeome 1.1 resource (Reboul *et al*., 2003) and Gateway-transferred into two mammalian expression vectors, in frame with sequences encoding either the GST or the Myc Tag, for DB-X baits (GST-X) and AD-Y preys (Myc-Y), respectively (Xu *et al*., 2003). In cotransfection experiments for which both GST-X and Myc-Y fusion proteins were expressed at detectable levels, the GST pull-down success rates were 82% for Core-1, 59% for Core-2, and 35% for Non-Core.

Since co-AP GST pull-down assays have a false-negative rate of their own owing to technical limitations different from Y2H (we only used a single binding condition, and proteins have been expressed from a single set of vectors), these results demonstrate that our datasets contain a large proportion of highly reliable interactions and confirm their relative quality. To our knowledge, this is the first time that the overall quality of a proteome-wide Y2H interactome mapping dataset was experimentally validated using an independent protein interaction assay.

Finally, until there is a precise and dynamic view of the whole proteome of an organism of interest, it will be virtually impossible to demonstrate that any two proteins found by Y2H do not interact in vivo. Thus, biological false-positives are extremely difficult to define and detect. However, increasing evidence for biologically genuine Y2H interactions can be obtained by accumulating experimental evidence emerging from other functional genomic or proteomic approaches (Vidal, 2001; Ge *et al*., 2003).

12. Overlap between interactome and transcriptome or phenome

Previous studies related interactome data to genome-wide expression (transcriptome) and phenotypic profiling (phenome) data in *S. cerevisiae* (Ge *et al*., 2001). However, would such correlations between different functional genomic datasets also hold for a multicellular organism, and could they help formulate biological hypotheses? To investigate this, we attempted to integrate our *C. elegans* interactome data with currently available transcriptome and phenome datasets.

Pearson correlation coefficients (PCCs), a metric used to assess a linear relationship between variables in two independent datasets, were calculated from the expression profiles described in the *C. elegans* transcriptome "Topomap" dataset (Kim *et al*., 2001) then compared between gene pairs involved in experimentally derived interactions in WI5 and gene pairs from randomized datasets. Approximately, 150 Core Y2H interactions ($\sim$10%) correspond to gene pairs with significantly higher PCCs than expected from random (p-value < 0.05). Those pairs can be considered as "more biologically likely" since two independent orthogonal approaches point to a functional relationship between the corresponding genes.

The remaining pairs are considered as "without corroborating evidence" by transcriptome analysis. Lack of coexpression does not suggest that the corresponding interactions are erroneous. Indeed, 75% of "literature" pairs, taken from published low-throughput interactions and hence considered biologically relevant, do not correlate with transcriptome data.

These results underscore some of the complexities inherent in attempting to overlap functional genomic data sets derived from metazoans. Unlike unicellular organisms, in metazoans, biological processes may occur differentially not just in single cells but also across different organs or tissues.

13. Functional and directional wiring diagrams of protein networks

Although combined functional genomic and proteomic maps provide biological hypotheses of gene function for many as yet uncharacterized gene products predicted from genome sequencing projects, they fail to provide a functional and directional model for protein networks. In other words, interactome maps do not indicate the functional consequences of the physical interactions detected. To address these issues, it will be necessary to carry out a systematic perturbation approach that consists of the generation of double knockouts (by RNAi knockdown, for example) of all pairwise combinations for a subgroup of genes suspected to be involved in a particular biological process.

Using *C. elegans* dauer formation, a developmental arrest decision during larval development in response to environmental stress, as an example, we tested the technologies required to generate functional and directional wiring diagrams of gene networks. After combining interactome, transcriptome, and phenome maps of the dauer regulatory network, starting from proteins known to be involved in the process, all pairwise combinations of double perturbations were created. We scored synthetic genetic interactions (i.e., double knockout gives rise to a more severe phenotype than either one alone) and epistatic relationships (two single knockouts giving rise to unlike phenotypes and the double gives rise to only one of these two phenotypes). We detected many such genetic interactions, and by mapping them into a wiring diagram, we are able to generate novel hypotheses about the dauer network (Tewari *et al*., 2004).

Thus, interactome maps can be used as a scaffold for the discovery of functional relationships between components of a particular biological process.

14. Toward a comprehensive analysis of biological networks

The development of technologies such as Gateway and HT-Y2H for manipulating large numbers of genes on the basis of the information obtained from genome sequencing and gene annotation efforts will enable scientists to begin asking biological questions related to how networks control developmental processes in normal and disease circumstances. However, this will be attainable only through

concerted efforts to create ORFeome collections for a wide variety of organisms, especially humans, and then utilize those ORFeomes for functional studies such as Y2H. The construction of the *C. elegans* ORFeome and its utilization for interactome mapping has provided a glimpse into how these efforts can be conducted for human studies and the challenges inherent in both creating and using such resources. Integration of information from multiple experimental platforms will be necessary to develop models of biological networks that can be both predictive and open to experimental manipulation.

Specialist Review

The yeast interactome

Peter Uetz
Institute of Genetics (ITG), Forschungszentrum Karlsruhe, Karlsruhe, Germany

Andrei Grigoriev
GPC Biotech, Martinsried, Germany

1. Introduction

The genome of the budding yeast *Saccharomyces cerevisiae* was the first eukaryotic genome to be sequenced. Therefore, yeast was also the first eukaryote whose complete set of proteins became known in 1996 (Goffeau *et al*., 1997). This led to the first systematic attempts to study protein interactions (the "interactome") and function at the end of the twentieth century. As a consequence, the yeast proteome and interactome are probably the best known of all eukaryotes, including human. As a guide to understanding a cell, the knowledge of its "interactome" is absolutely necessary as protein interactions are critical to all processes in biology. Here we summarize current knowledge of the yeast interactome and some of its implications for other model systems.

1.1. *Types of interaction data: sources and classification*

Historically, that is, until the yeast genome sequence became available, proteins and their interactions were studied one by one as they were identified in genetic screens or by other methods. However, the availability of the genome sequence allowed the study of all yeast proteins in a systematic way and as a consequence, the majority of our current knowledge of the yeast interactome stems mostly from a few large-scale studies. These studies included the yeast *two-hybrid* assay (Figure 1) and the purification of protein complexes and their analysis by *mass spectrometry* (*see* Article 4, **Interpreting tandem mass spectra of peptides**, Volume 5 and Article 36, **Biochemistry of protein complexes**, Volume 5). More recently, *genetic screens* also yielded a large number of interactions, but it remains unclear how many of those represent physical interactions (see below for details). Nevertheless, detailed "small-scale" studies remain extremely important as they still provide the only means for careful functional analysis and the placement of interaction data in a biological context.

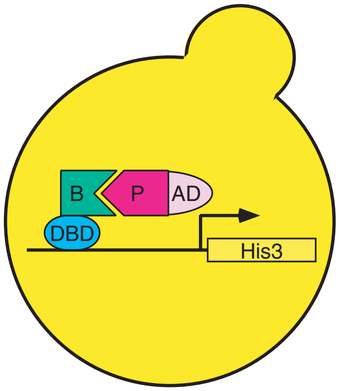

Figure 1 *The two-hybrid system* is based on the expression of two fusion (i.e., two hybrid) proteins in a cell. One of the fusion proteins contains a DNA-binding domain (DBD), which can bind to the promoter of a reporter gene (here: His3), and a "B" protein ("bait"). The second fusion protein consists of a transcription activation domain and an ORF protein (open reading frame, any protein). If B interacts with ORF, a transcription factor is formed, which can switch on the reporter gene. This enables the cell to grow on a histidine-free medium (the endogenous His3 gene has to be deleted). Hence, a growing yeast colony indicates that the two expressed proteins interact. If they do not interact, no colony is formed

2. Methods for interaction analysis and their data

2.1. *Two-hybrid interactions*

The two-hybrid system uses two hybrid proteins, which reconstitute a transcription factor when they interact. This transcription factor can switch on a reporter gene (Figure 1). Two-hybrid interactions are usually binary although occasionally a third protein may mediate interactions between the two hybrids. For yeast, there are about 7000 two-hybrid protein interactions available in databases derived from small and large-scale screens (Table 1).

The first large-scale study (Uetz *et al*., 2000) included two independent screens: one tested 192 baits for interactions with all 6000 yeast proteins and found 281 reproducible interactions for 87 proteins. In the second screen, all ~6000 activation domain constructs were pooled and tested against each DNA-binding domain fusion (Figure 1), resulting in 692 interactions involving 817 proteins.

Ito *et al*. (2001) presented the largest two-hybrid interaction screen to date, which detected 4549 interactions among 3278 proteins. Of these, 841 were found four or more times and they represented a "core" subset of more reliable interactions.

2.2. *Protein complex purification and analysis by mass spectrometry*

Often, proteins interact within stable protein complexes (*see* Article 35, **Structural biology of protein complexes**, Volume 5 and Article 36, **Biochemistry of protein**

Table 1 Large-scale and examples of smaller studies of protein–protein interactions in yeast

Method (proteins)	Interactions	References
Y2H	~4500	Ito *et al*. (2001)

Purification + MS	~33 000[b]	Ho *et al*. (2002)
Synthetic lethality	~4000	Tong *et al*. (2004)
Combined large- and small-scale collections	~15 700	From DIP database
	~12 700	From MINT database
	~15 500	From MIPS database

[a]59 interactions were common to both approaches and therefore considered as highly likely. PD = phage display; MS = mass spectrometry.
[b]Counting all-against-all possible interactions between complex members in filtered datasets (matrix model), actual numbers of protein–protein interactions cannot be determined from the data.

complexes, Volume 5). These complexes can be purified and their components identified. In contrast to two-hybrid data, this provides no or little information on which subunit interacts with which other subunit. Two-hybrid data, on the other hand, do not tell which interactions lead to a stable complex (Figure 2).

Two large-scale studies identified protein complexes in yeast. Gavin *et al*. (2002) analyzed 1739 genes, including 1143 human orthologs, and identified 232 distinct multiprotein complexes using tandem affinity purification (TAP) (Figure 3). This set of proteins was not representative as it contained many highly conserved proteins and so we cannot conclusively extrapolate these numbers to the whole yeast proteome. However, these results suggest that there may be no more than 400 or 500 complexes in yeast, although many of them cannot be precisely defined as some of their subunits may vary.

A more conclusive number may become available through the analysis by Emili *et al*. (personal communication), who have continued the analysis of Ho *et al*. and purified a total of 4455 TAP-tagged baits of which more than 3400 resulted in successful purifications. However, an analysis of this dataset was not available at the time of this writing.

Ho *et al*. (2002) chose an initial set of 725 bait proteins and identified the proteins associated with these baits using a Flag epitope tag in the high-throughput mass spectrometric protein complex identification (HMS-PCI). After removal of potential false positives, this filtered data set contained 1578 different interacting proteins.

Two models are used to map complexes to pairwise interactions. The *spoke model* assumes that the bait protein interacts with all other proteins in the complex. The *matrix model* assumes that every protein in a complex interacts with every other protein, that is, there are $N(N-1)/2$ interactions in a complex containing

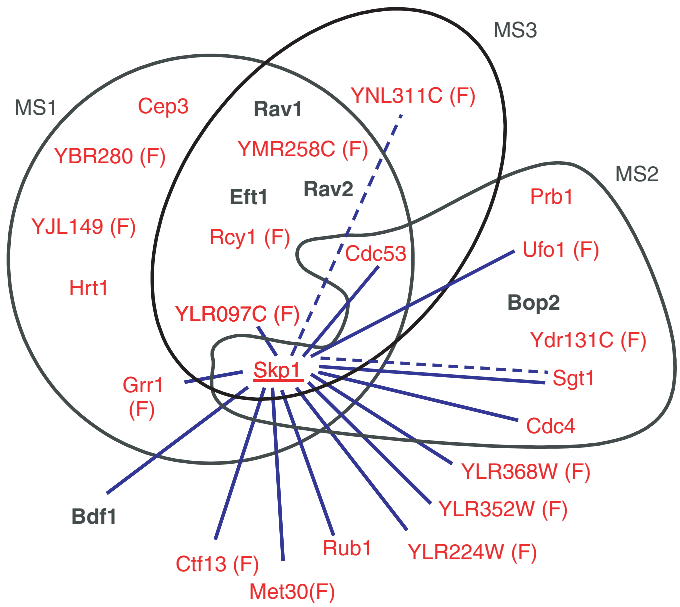

Figure 2 *Two-hybrid versus protein complex data.* Skp1 is a protein involved in ubiquitin-mediated protein degradation and has been used as bait for two-hybrid screens and epitope-tagged for mass spectrometry analysis. The purified complexes of Skp1 from three independent MS studies (MS1–3) and the binary interactions from two Y2H studies (solid and broken blue lines) are compared. Despite the differences in the data sets, most of the interactions found seem to be plausible: All proteins colored red are known to be involved in protein degradation. Skp1 is directed to its target proteins via so-called F-box proteins, which contain a short peptide motif, the F-box (F). For details, see Titz *et al*. (2004)

N proteins. These models represent theoretical minimum and maximum numbers of interactions and are both correct only if a complex is a heterodimer. The real topology of the interactions in a complex is most likely somewhere in between these extremes. When compared to a literature benchmark, one of the matrix models had turned out to be three times more incorrect than the spoke (Bader and Hogue, 2002), although other studies have not found any significant difference (Cornell *et al*., 2004).

A graphical representation of complexes yields a fairly intricate display of interconnections between individual bait-target groups (Figure 4).

2.3. *Genetic interactions and synthetic lethality*

Single mutations often do not affect the viability of a cell significantly. However, if two or more such mutations are combined, this may have a much more severe effect than expected from the individual mutants or may even cause lethality. Genes that exhibit such a synthetic phenotype are said to interact genetically. In many cases, the products of these genes are components of a complex, a pathway, or are otherwise functionally related (e.g., compensate each other’s function). Therefore,

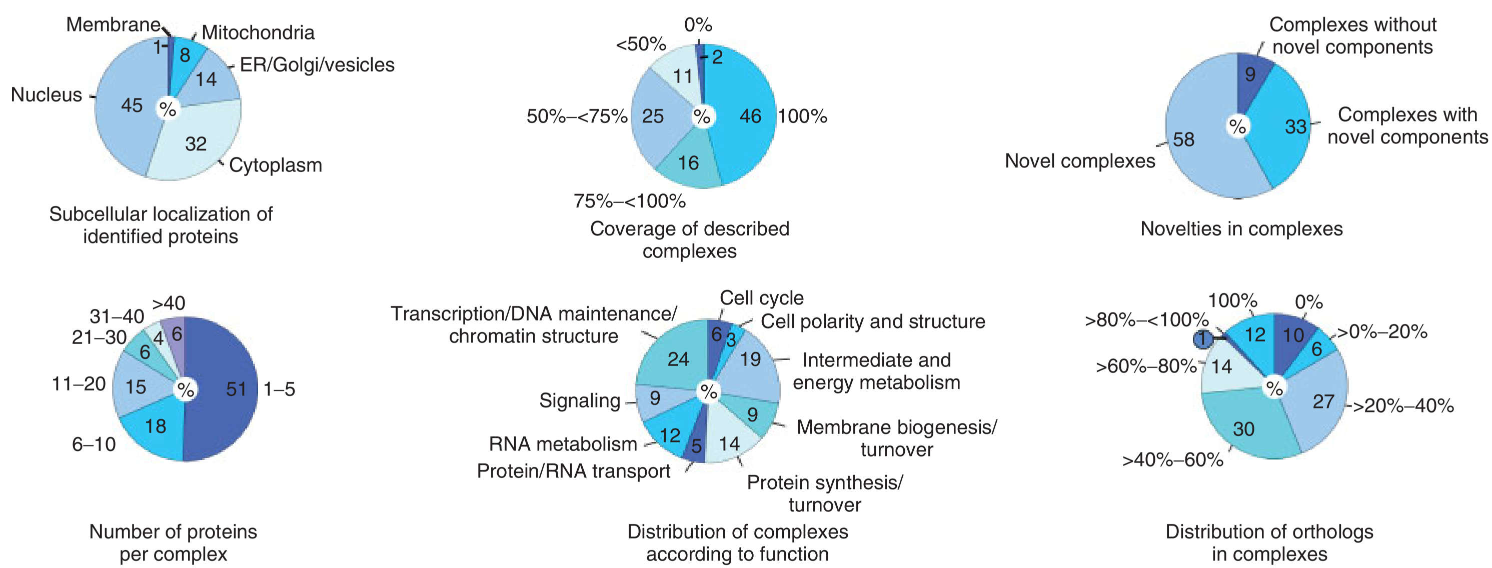

Figure 3 *Statistics of proteins and complexes.* Numbers inside pie charts represent the percentages of total proteins (a) and complexes (b–f) based on the data published by Gavin *et al*. (2002). Outer labels show partitioning of the data according to the chart function. (b) indicates the coverage of protein complexes when compared to the known complexes, as cataloged in the Yeast Protein Database (YPD). For example, 46% of the complexes contained all known (100%) components of these complexes. (f) shows the conservation of proteins in complexes as defined by the presence of orthologs. For example, 27% of the complexes contained 20–40% human orthologs and 10% of the complexes did not contain any human orthologs. (Reprinted with permission from Nature (Gavin *et al*.) ©2002 Macmillan Magazines Limited)

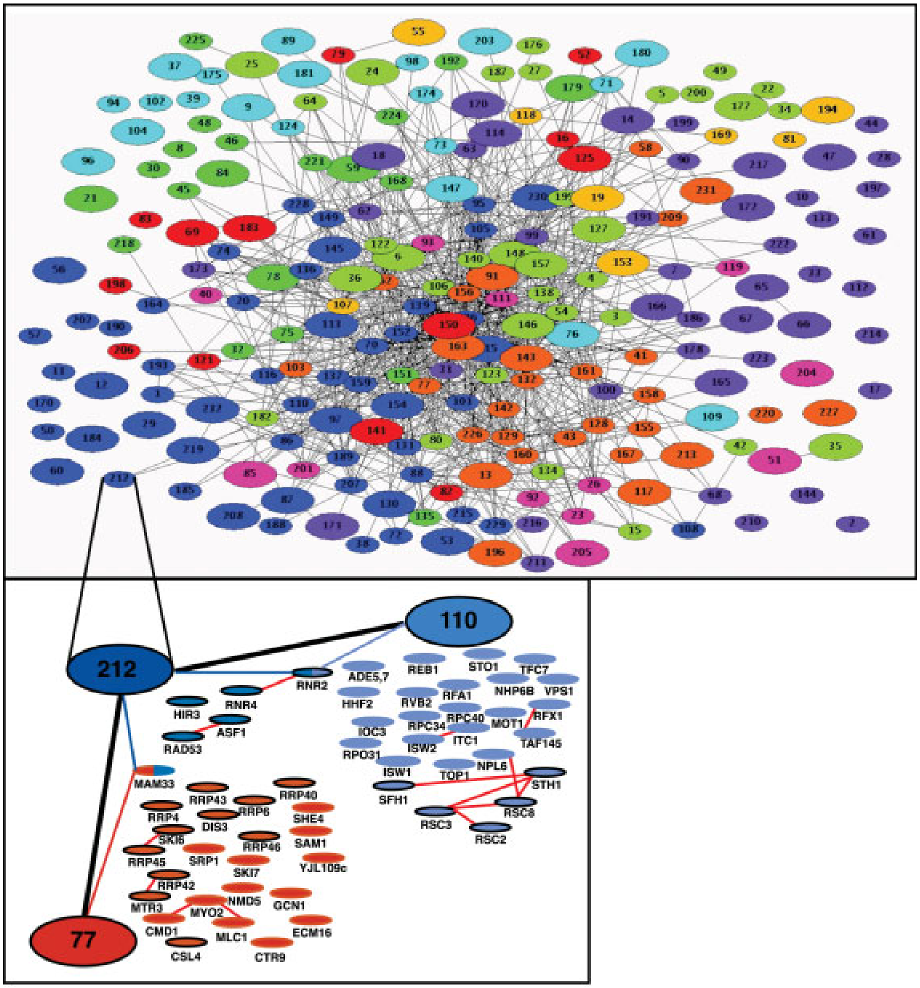

Figure 4 *The protein complex network, and grouping of connected complexes.* Links were established between complexes sharing at least one protein. For clarity, proteins found in more than nine complexes were omitted. The graphs were generated automatically by a relaxation algorithm that finds a local minimum in the distribution of nodes by minimizing the distance of connected nodes and maximizing the distance of unconnected nodes. In the upper panel, cellular roles of the individual complexes are color coded: red, cell cycle; dark green, signaling; dark blue, transcription, DNA maintenance, chromatin structure; pink, protein and RNA transport; orange, RNA metabolism; light green, protein synthesis and turnover; brown, cell polarity and structure; violet, intermediate and energy metabolism; light blue, membrane biogenesis and traffic. The lower panel is an example of a complex (yeast TAP-C212) linked to two other complexes (yeast TAP-C77 and TAP-C110) by shared components. It illustrates the connection between the protein and complex levels of organization. Red lines indicate physical interactions as listed in YPD22. (Reprinted with permission from Nature (Gavin *et al.*) ©2002 Macmillan Magazines Limited)

such combined mutations often lead to an additive or even stronger effect. However, the proteins do not need to interact physically in order to show such a synthetic phenotype.

Tong *et al*. (2004) presented the largest analysis of synthetic lethal interactions so far. Their 132 SGA (i.e., "synthetic genetic analysis") screens focused on query genes involved in actin-based cell polarity, cell wall biosynthesis, microtubule-based chromosome segregation, and DNA synthesis and repair, detecting 4000 interactions amongst 1000 genes. It suggests that the yeast synthetic genetic network may contain up to 100 000 interactions although 24 000 appear more realistic based on the biased choice of genes studied. Approximately 20% of the query genes (not included in the 132 query genes mentioned above) showed no genetic interactions. The frequency of false negatives was estimated to be in the range of 20–40%.

2.4. *Other physical methods*

Protein interactions have been identified using a number of different methods including coimmunoprecipitation, protein arrays (*see* Article 24, **Protein arrays**, Volume 5), FRET (*see* Article 51, **FRET-based reporters for intracellular enzyme activity**, Volume 5), or structural biology (Section (7)). However, none of these methods has been used on a large scale to identify protein interactions although such projects are under way, especially in structural genomics (*see* Article 97, **Structural genomics – expanding protein structural universe**, Volume 6) and using protein arrays (Zhu *et al*., 2001; *see also* Article 24, **Protein arrays**, Volume 5).

3. Data quality

Many interactions from large-scale studies are not as rigorously quality controlled as from small-scale experiments. This is true for both two-hybrid and mass spectrometry analyses. Various studies estimated that two-hybrid data may have 50–90% false positives (Mrowka, 2001; Sprinzak *et al*., 2003), while mass spectrometry datasets may have >30% false positives (Gavin *et al*., 2002). The reason for two-hybrid false positives is not well understood but it somehow derives from unspecific activation of the reporter genes used. Mass spectrometry may result in false positives if the complexes are not highly purified. On the other hand, stringent purification may result in false negatives as subunits are lost. However, smaller-scale screens also detected interactions which are not in agreement with structural data (Edwards *et al*., 2002), indicating a need in the integration of diverse types of data to confirm interactions by other means.

Other approaches to assessment of interaction datasets have included analysis of orthologs (Deane *et al*., 2002; Pagel *et al*., 2004), gene expression (Kemmeren *et al*., 2002), and network topology (Saito *et al*., 2002; Goldberg and Roth, 2003). A comprehensive dataset of putative yeast interactions was collected by von Mering *et al*. (2002) from a large number of sources including two-hybrid and complex pull-down results, smaller-scale studies and in silico predictions (including conserved gene neighborhood, gene fusion events and co-occurrence of genes as well as correlated mRNA expression). The gene pairs collected have been assigned

confidence on the basis of the number of sources of supporting evidence, with the high-confidence set supported by at least two sources including about 2500 interactions between some 1000 proteins.

Interestingly, homologous protein interactions found in two species appear to be more reliable than interactions found by two independent methods (Lehner and Fraser, 2004).

4. Comparison of various interaction datasets

Various high-throughput projects produced surprisingly different results. Biologists need to be aware of these differences as they indicate important limitations of different approaches (Cornell *et al*., 2004).

4.1. Mass spectrometry data

In mass spectrometry approaches, of 115 common baits used by TAP (Gavin) and HMS-PCI (Ho) only 47 retrieved complexes containing common proteins. In 33 other complexes with the same bait, there was no other common member. As a result, there is considerable disparity between the size and content of complexes generated by TAP and HMS–PCI.

The TAP approach was also more successful at identifying reverse interactions than HMS–PCI. In 39% of instances where B is used as a bait, it identified A, compared to 19% for HMS–PCI.

4.2. Two-hybrid data

There are 220 bait proteins in common between the two large-scale screens. For these baits, the Ito dataset contains 871 interactions, while that of Uetz contains 430; 164 interactions were common to both datasets. The Ito dataset contains many highly connected proteins (HCPs) several of which interact with more than 100 preys. Of the 2161 HCP interactions, only 67 (3.1%) have been verified by multiple datasets. Most studies therefore agree that such interactions consist mostly of false positives. Uetz *et al*. (2000) filtered out such HCPs as false positives.

In addition, in the vast majority of cases, unverified interactions were identified with the HCP as the bait protein. In only 221 of the 2161 interactions is the HCP the identified protein.

4.3. Transient versus stable interactions

Aloy and Russell (2002) noticed that mass spectrometry studies appear to identify preferentially stable interactions while two-hybrid studies tend to prefer transient interactions. Transient interactions also occur more frequently in HMS–PCI data than in TAP data, which may be due to a more rigorous washing regime than in the HMS–PCI procedure.

5. Integrating protein–protein interactions with other datasets

The first attempt at integrating the yeast proteome data was the study of a relationship between gene expression and protein interactions (Grigoriev, 2001).

Protein pairs encoded by coexpressed genes were found to interact with each other more frequently than random protein pairs. This approach allows one to evaluate interaction datasets using large-scale gene expression profiling as benchmark. For example, the MIPS collection, with interactions collected from literature and often supported by additional evidence, has shown by far the best agreement with gene expression profiles than large-scale interaction screens. Similarly, the "core" subset from Ito *et al*. (2001) has shown better agreement than the rest of their interactions. These findings were supported by a number of follow-up papers (Ge *et al*., 2001; Jansen *et al*., 2002; Kemmeren *et al*., 2002; Deane *et al*., 2002). Cornell *et al*. (2004) compared protein pairs co-occurring in multiple TAP/HMS–PCI complexes with the pairs detected only once and found the former to display a much stronger correlation with gene expression data.

Note that correlation of mRNA expression is not necessary for protein interaction, that is, proteins whose expression is not correlated strongly may still be bona fide interactors as long as they coexist in sufficient proximity within a cell.

Integration of various datasets remains a tremendous challenge for bioinformatics, especially when interactions have to be displayed graphically together with expression data, homology, structures, or localization in a cell (Uetz *et al*., 2002).

6. The yeast interaction network

When the results of large- and small-scale two-hybrid screens were put together, the resulting network surprisingly connected almost all yeast proteins (Figure 5); only a few proteins resulted in smaller networks that were not linked to the large component (Schwikowski *et al*., 2000). Such interaction networks have led to a flurry of bioinformatic studies, exploring the topology and biological significance of its properties. Here, we summarize only a few interesting results and refer the reader to the literature for more detailed analysis (Barabasi and Oltvai, 2004; *see also* Article 111, **Functional inference from probabilistic protein interaction networks**, Volume 6).

6.1. Computational identification of protein complexes in networks

Several studies have demonstrated that complexes can be found in networks by searching for local clusters of interacting proteins (Bader and Hogue, 2003; Krause *et al*., 2003; Spirin and Mirny, 2003; Bu *et al*., 2003). Given that many proteins are shared by several complexes, these findings blur the distinction between defined complexes and whole proteome interaction networks and emphasize the dynamics of protein interactions within a cell.

6.2. Modularity of the protein interaction network in yeast

Early topological analyses of metabolic networks indicated that they can be considered as modular. The same seems to be true for protein interaction networks

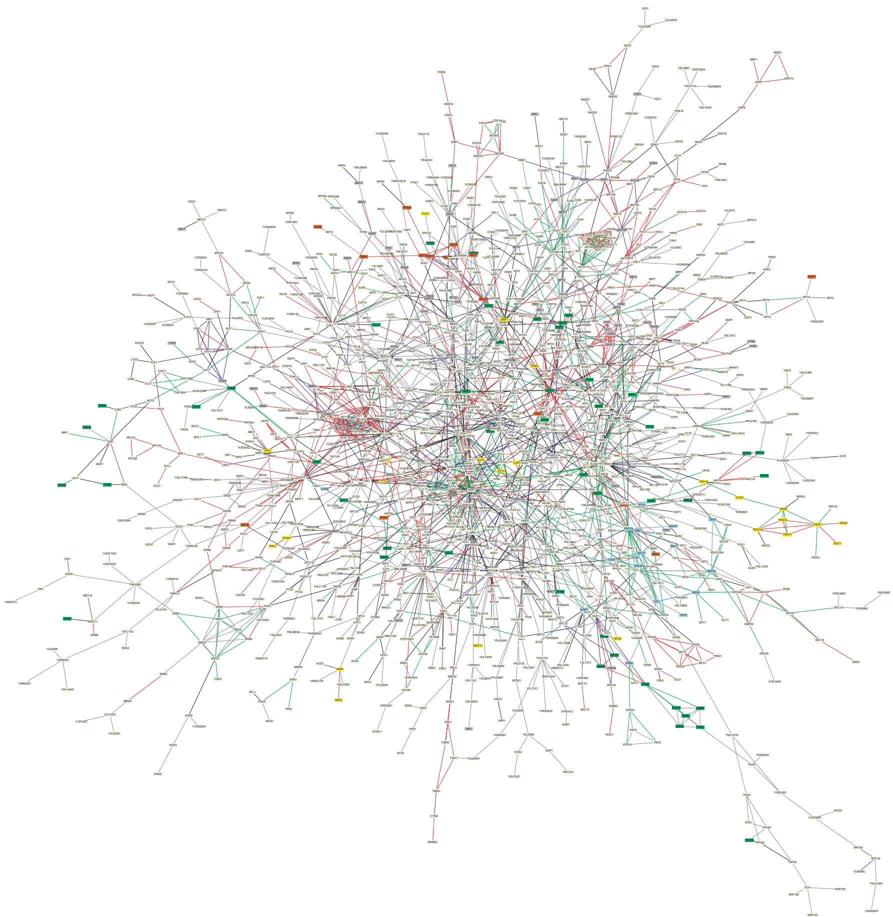

Figure 5 *An interaction map of the yeast proteome assembled from published interactions.* The map contains 1548 proteins and 2358 interactions. Proteins are colored according to their functional role as defined by the Yeast Protein Database (YPD); proteins involved in membrane fusion (blue), chromatin structure (gray), cell structure (green), lipid metabolism (yellow), and cytokinesis (red). After Schwikowski B, Uetz P and Fields S (2000) A network of protein-protein interactions in yeast. *Nature Biotechnology*, **18**, 1257–1261. (Reproduced by permission of Nature Publishing Group)

(Figure 6). Han *et al*. (2004) identified two classes of highly connected proteins (hubs): *party hubs* (that interact mostly within a protein complex) and *date hubs* (interacting with other hubs, mainly transiently but not in stable complexes).

Averaging Pearson correlation coefficients (PCCs) of mRNA expression between hubs and their interaction partners produced a bimodal distribution for expression data related to various biological functions such as "stress response" and the "cell cycle" (Figure 6b). Other expression groups did not show such a clear bimodal distribution. After excluding ribosomal hub proteins, these two peaks of the distribution contained 91 date (lower PCCs) and 108 party hubs (higher PCCs) in the high-confidence interaction dataset of von Mering *et al*. (2002).

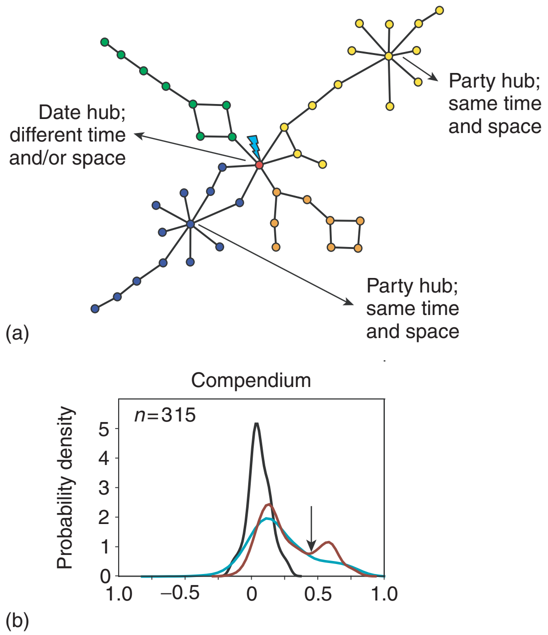

Figure 6 *Date and party hubs*. Probability densities of the average Pearson correlation coefficients (PCCs) were calculated from a global expression profiling compendium. The number n refers to the number of data points for each gene for each condition. No bimodal distribution is observed with the average PCCs of nonhub proteins (cyan curve) or for hubs in randomized networks (black curve). (Reprinted with permission from Nature (Han *et al*.) ©2004 Macmillan Magazines Limited)

Interestingly, changes in the network connectivity resulting from removal of the party hubs (involved in complexes) were similar to those resulting from removal of random proteins, whereas deletion of date hubs produced much more serious changes in network connectivity. Finally, date and party hubs are threefold more likely to be essential than nonhubs, but their individual knockout affects cellular viability to the same extent.

7. Which proteins do interact (or do not?)

As expected, most proteins interact with functionally related and colocalized proteins. In the interaction network (Figure 5), proteins of the same function and cellular location tend to cluster together, with 60–75% of the interactions occurring between proteins with a common functional assignment/same subcellular compartment. When proteins are grouped by functional role or subcellular compartment, interesting patterns of crosstalk between groups can be seen (Figure 7).

However, the tendency to interact at all is different among different functional classes. Signaling proteins or proteins within protein complexes need to interact with multiple proteins while enzymes tend to interact only with few proteins if at all (they rather interact with low-molecular weight substrates). With respect

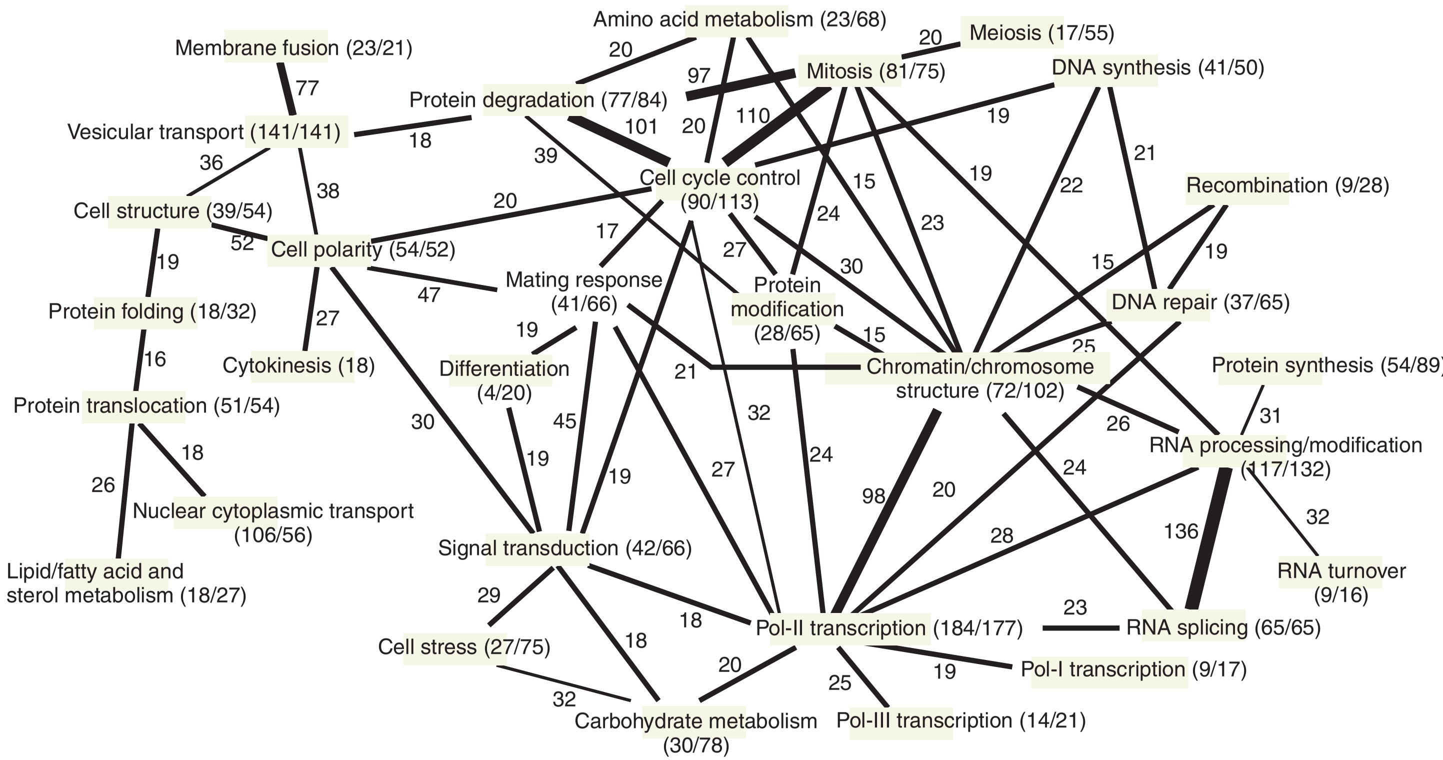

Figure 7 *Interactions between functional groups*. Numbers in parentheses indicate, first, the number of interactions within a group, and second, the number of proteins in a group. Numbers near connecting lines indicate the number of interactions between proteins of the two connected groups. For example, there are 77 interactions between the 21 proteins involved in membrane fusion and the 141 proteins involved in vesicular transport (upper left corner); 23 protein interactions connect the 21 proteins involved in membrane fusion. Only connections with 15 or more interactions are included here. Note that only proteins with known function are shown (many of these have several functions). The sum of all interactions in this diagram is therefore smaller than the number of all interactions. After Schwikowski B, Uetz P and Fields S (2000) A network of protein-protein interactions in yeast. *Nature Biotechnology*, **18**, 1257–1261. (Reproduced by permission of Nature Publishing Group)

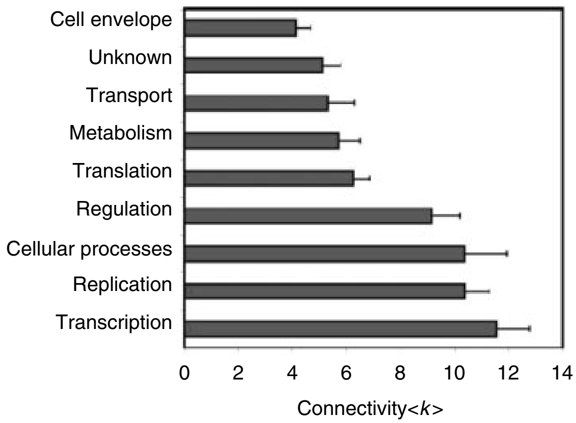

Figure 8 *Average connectivity levels k of functional classes.* Error was estimated from 100 random samplings of each functional class with 50 proteins each. After Kunin V, Pereira-Leal JB and Ouzounis CA (2004) Functional evolution of the yeast protein interaction network. *Molecular Biology and Evolution*, **21**, 1171–1176. (Reproduced by permission of Oxford University Press)

to *function*, proteins involved in the yeast cell envelope appear as the least connected, followed by unknown proteins, and proteins involved in transport and metabolism. At the other extreme, proteins involved in transcription, replication, cellular processes, and regulatory functions have, on average, almost twice as many binding partners. Interestingly, proteins of unknown function ("Unknown" functional class) are close to the lower end of connectivity, a trend that has been observed already in some of the initial high-throughput interaction screens (Uetz *et al*., 2000).

Figure 8 summarizes the average connectivity of proteins of various functional classes.

8. Evolution and conservation of protein complexes and interactions

Gavin *et al*. (2002) showed that many protein complexes are conserved between yeast and human, even if the proteins have only limited sequence homology. Teichmann (2002) showed that homologous proteins involved in such complexes share 46% sequence identity between *S. cerevisiae* and *S. pombe*, while proteins not known to be involved in complexes share 38% identical amino acids. This is not a huge difference and false-positive interactions have been used to explain why highly connected proteins are not subject to more evolutionary constraints (Wagner, 2001; Hahn *et al*., 2004).

Pagel *et al*. (2004) detected a correlation between the number of interaction partners of a yeast protein and its likelihood of having an ortholog in other ascomycota species.

Surprisingly, the proteins of oldest origin (i.e., proteins that are conserved across most species) do not display the highest connectivity (Kunin *et al*., 2004). This

is in contrast to the prediction of the preferential attachment model that oldest proteins are expected to display the highest levels of connectivity (Albert and Barabasi, 2000). The majority of the most highly connected proteins are found to have emerged during the eukaryotic radiation. Although Kunin *et al*. (2004) observed that the most recent proteins tend to be of lower connectivity, they failed to detect the steady increase of connectivity with the protein age.

Structurally, Aloy *et al*. (2003) found that close homologs (30–40% or higher sequence identity) almost invariably interact the same way, that is, with the same interaction surfaces. This similarity cutoff correlates well with the conservation of function that appears to be almost complete above a threshold of about 40% amino acid identity.

9. How many protein interactions are there in yeast?

The fact that neither of the two studies by Uetz *et al*. and Ito *et al*. recapitulated more than 13% of the published interactions detected by the community of yeast biologists indicates that there are many more interactions remaining to be discovered.

Using approaches ranging from an educated guess to probabilistic modeling of large-scale two-hybrid screens, various authors estimated the lower and upper boundaries for the number of protein interactions in yeast to be around 10 000 and 30 000 interactions (Figure 9).

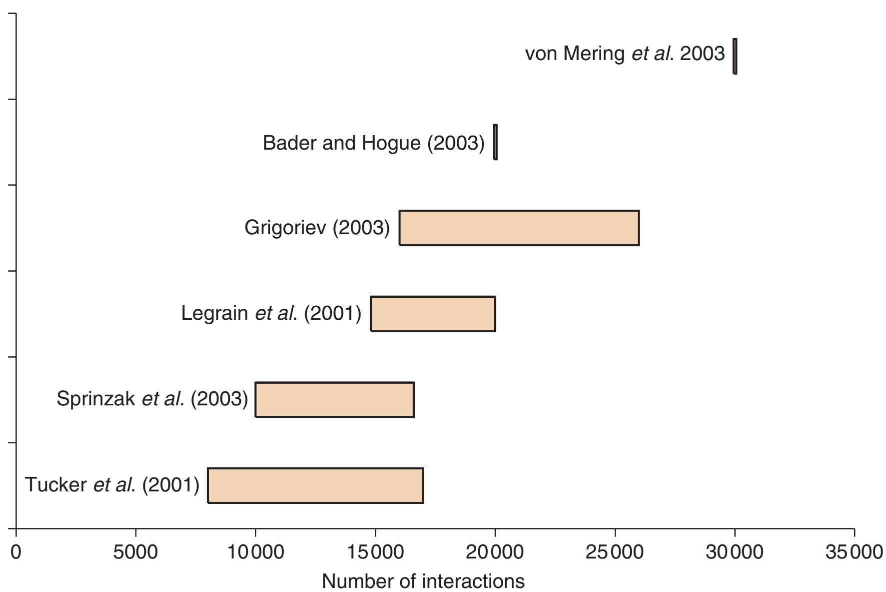

Figure 9 *Estimates of the size of the yeast interaction network, excluding homotypic interactions.* Numbers and ranges are as in the original publications (von Mering, 2002; Bader and Hogue, 2003; Grigoriev, 2003; Legrain *et al*., 2001; Sprinzak *et al*., 2003), not taking into account the changes in the estimated number of the yeast genes (for details see Grigoriev, 2004)

10. Biological relevance of protein interactions

Many protein interactions are absolutely essential. However, it remains unclear which fraction of interactions are really necessary on a global scale. Jeong *et al*. (2001) investigated an yeast interaction network with 1870 proteins as nodes, connected by 2240 direct physical interactions, and found that the scale-free nature of the network makes it relatively error-tolerant, at least when the diameter of the network is measured (i.e., the average distance between two random proteins). Single random mutations in the genome of *S. cerevisiae*, modeled by the removal of randomly selected yeast proteins, do not affect the overall topology of the network. By contrast, when the most connected proteins are computationally eliminated, the network diameter increases rapidly. The likelihood that removal of a protein will prove lethal correlates with the number of interactions the protein has. For example, although proteins with five or fewer links constitute about 93% of the total number of proteins, Jeong *et al*. found that only about 21% of them are essential. By contrast, only some 0.7% of the yeast proteins with known phenotypic profiles have more than 15 links, but single deletion of 62% or so of these proves lethal.

Short Specialist Review

Human signaling pathways analyzed by protein interaction mapping

Frédéric Colland
Hybrigenics SA, Paris, France

Pierre Legrain
CEA Saclay, Gif-sur-Yvette, France

The generation of protein interaction maps can provide initial insight into cellular mechanisms. The study of such maps can be used as a means of suggesting the functions of hundreds of previously uncharacterized genes (*see* Article 39, **The yeast interactome**, Volume 5). Most protein interaction maps have been developed with the yeast two-hybrid system (Legrain *et al*., 2001), the complex pull-down approach involving the coimmunoprecipitation of proteins followed by mass spectrometry (Gavin *et al*., 2002; *see also* Article 36, **Biochemistry of protein complexes**, Volume 5) or the phage display method (Tong *et al*., 2002). However, these systems present a challenging technical problem in that the resulting datasets contain large numbers of irrelevant interactions due to the use of high-throughput methods. Biological validation of protein interaction networks is therefore required, by integrating heterogeneous data, such as those relating to expression profiling, genetic data, phenotypic analyses, protein localization, or published functional annotations. However, only limited amounts of information are currently available for most of the proteins encoded in the human genome, suggesting that functional annotations will remain limited or uncertain for a large proportion of protein networks.

The putative functions of proteins involved in the interaction network can be validated by means of cellular assays. Such studies have been performed in *Caenorhabditis elegans*, with the establishment of protein interaction maps for DNA damage response (Boulton *et al*., 2002) and DAF7/TGFβ signal transduction (Tewari *et al*., 2004), followed by functional validation (*see* Article 38, **The *C. elegans* interactome project**, Volume 5). However, to date, only specific studies focusing on a very limited set of proteins and interactions have been carried out for mammalian proteins (Boeda *et al*., 2002). A key limitation is the difficulty involved in handling the large number of interactions identified, together with the numerous specific functional analyses required to demonstrate the biological function of each newly identified protein and/or interaction. Two recent studies combined protein interaction

mapping with functional validation assays. The first dealt with the TNF-α/NF-κB signal transduction pathway (Bouwmeester *et al*., 2004) and the second with the human Smad signaling pathway (Colland *et al*., 2004). In these two studies, protein interaction mapping, carried out with different technologies, led to the generation of large datasets, which were explored with the help of the functional annotations available in public databases. The global validation of protein networks was achieved by identifying well-known proteins involved in these pathways. A subset of proteins, as yet poorly annotated or functionally unrelated to these pathways, was then selected for study in cellular assays, with loss-of-function and overexpression analyses, to confirm the involvement of these proteins in these pathways.

TNF-α triggers a signaling cascade that converges on activation of the transcription factor NF-κB. Bouwmeester and coworkers used a complex pull-down technique derived from the tandem affinity purification method developed for yeast protein complex analyses (Rigaut *et al*., 1999) to identify proteins that copurified with 32 known and candidate components of this pathway. An initial dataset of 680 protein associations was constructed. It should be noted that the complex pull-down method does not identify individual protein–protein contacts but instead identifies groups of proteins in stable association. In this dataset, they identified 70% of the previously reported interactions with the original 32 proteins; the success rate for the detection of known interactions was therefore fairly high. Thorough statistical analysis of the dataset led to the selection of a subset of 131 for which interactions were predicted to occur with a high level of confidence. Eighty proteins in this dataset were not well characterized or were unrelated to the TNF-α/NF-κB signal transduction pathway and may therefore correspond to previously unidentified components of this pathway. Twenty-eight proteins were chosen for further functional characterization in an RNAi gene expression perturbation assay, with phenotypic effects monitored on an NF-κB-dependent luciferase reporter readout. Ten of these 28 candidates displayed a decrease in luciferase activity, consistent with a role in the modulation of TNF-α/NF-κB signal transduction.

In an independent study, Colland and coworkers investigated the human Smad signaling pathway (Colland *et al*., 2004). Members of the TGFβ superfamily (e.g., TGFβ, activins, and bone morphogenetic proteins (BMPs)) are secreted signaling molecules that regulate many biological processes, including cell growth, differentiation, and morphogenesis. The disruption of components of the TGFβ superfamily pathways is associated with human diseases including fibrosis, inflammatory disorders, and cancer. The effects of these pleiotropic molecules are transduced via various kinase receptors and Smad transcription factors, which regulate target gene expression in collaboration with other transcriptional partners (Massague, 1998).

Protein–protein interactions involving 23 Smad and related proteins were screened with the yeast two-hybrid system. Protein complexes were not characterized but individual contacts between proteins were identified (Figure 1). A complex network of 755 interactions involving 591 proteins was generated. A dedicated navigation tool for protein interaction maps was used to explore and analyze such complex interaction databases (the PIMRider®, (Rain *et al*., 2001)). The network includes 18 known Smad-connected proteins and 179 poorly or unannotated proteins. The yeast two-hybrid method used in this study makes it possible to

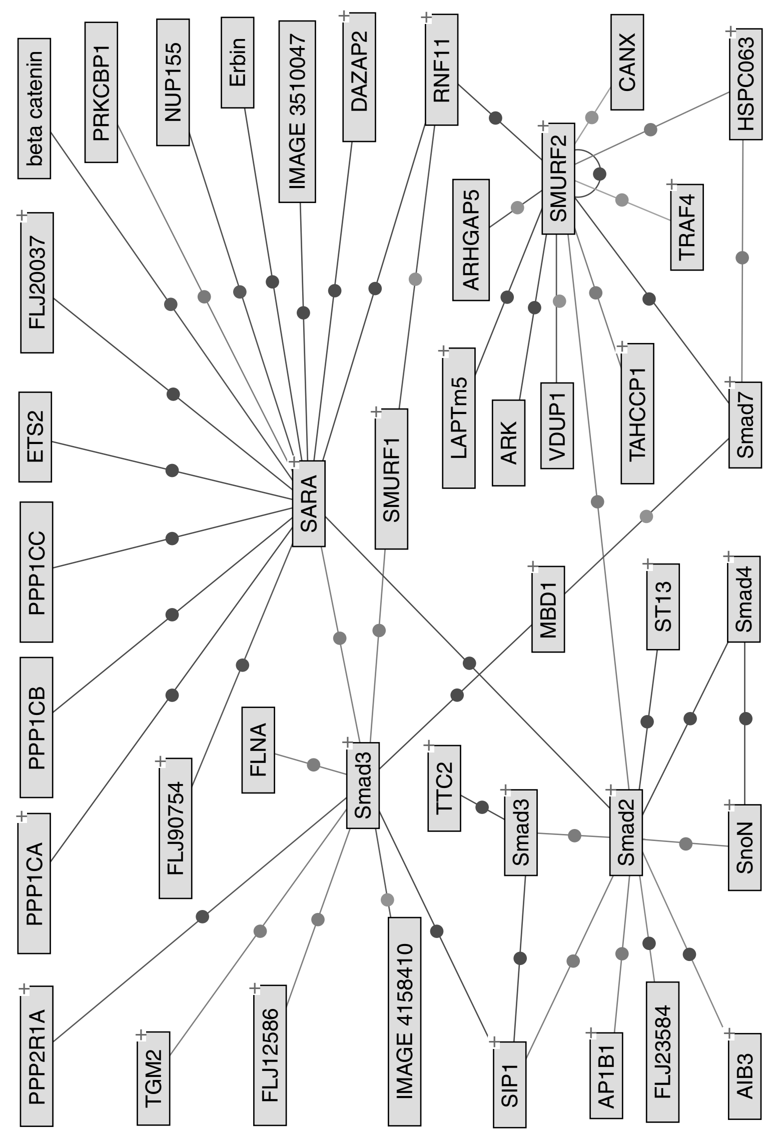

Figure 1 Partial protein interaction network for the Smad pathway

identify the fragment of the protein that contains the interacting domain ("selected interacting domain" or SID®). These SIDs and the functional domains of each given protein are displayed in PIMRider, facilitating thorough searches for correlations between characterized interaction motifs and selected interacting domains. Each protein–protein interaction pair is also characterized by a confidence score based on a statistical model, reflecting the reliability of identified interactions in the context of the full dataset.

Fourteen proteins were selected on the basis of interaction scores and functional domain annotations. These proteins were tested for their involvement in the Smad pathway by loss-of-function and overexpression studies in mammalian cells. Using Smad-specific reporter genes and Smad-dependent endogenous target genes as readout, eight of these 14 proteins were found to be associated with the Smad-related signal transduction. Four of these eight proteins (PPP1CA, ZNF8, MAN1, and RNF11) have independently been shown to be involved in the Smad pathway by other groups (Bennett and Alphey, 2002; Jiao *et al*., 2002; Raju *et al*., 2003; Subramaniam *et al*., 2003). The other four proteins (KIAA1196, HYPA, LMO4, and LAPTm5) have unknown functions or are poorly characterized, and biological functions could be suggested for these proteins. For example, the *LAPTm5* gene is upregulated by TGFβ and the LAPTm5 protein acts as a negative regulator of the TGFβ pathway. These findings, combined with the LAPTm5 interaction data, suggest that LAPTm5 may act as a smurf2 receptor in the lysosomal membrane and may target some TGFβ signaling components to the lysosomal compartment for degradation (Colland, 2004).

These two studies demonstrate that a large-scale protein–protein interaction map, combined with functional validation in mammalian cells, can be used to identify new components of signal transduction pathways. Clearly, such studies cover only a limited number of the potential interactions between human proteins. However, questions may be raised concerning the quality of datasets generated in studies aiming to cover the complete proteomes of complex organisms and the experimental methods currently available for the functional validation of such datasets. Focused studies, such as those summarized here, involve tens of proteins and generate protein interaction maps including hundreds of interactions. In-depth analyses of these datasets have led to the selection of tens of putative new components of signaling pathways. About half these candidates turn out to be functionally related to the expected pathways. Protein interaction maps generated at the whole-genome scale have recently been published for complex organisms such as the nematode *C. elegans* (Li *et al*., 2004; *see also* Article 38, **The *C. elegans* interactome project**, Volume 5) and the fruit fly *Drosophila melanogaster* (Giot *et al*., 2003). These two exhaustive studies generated genome-wide protein interaction maps connecting 3000 proteins via 5500 interactions for *C. elegans* and 5000 proteins via 5000 interactions for *Drosophila*. Given that these genomes each encode more than 10 000 proteins, these maps provide a much lower level of coverage than those based on a more focused set of proteins. With such a low density of information, associated with a presumably high frequency of false–positives, poor annotations of large parts of the networks are likely to preclude the design of further functional validation experiments, which are required to confirm the annotation made for each protein.

In conclusion, extensive functional proteomic studies, combining large-scale protein interaction mapping with functional assays, focusing on specific cellular functions or processes should considerably increase our knowledge about many human genes that are still poorly annotated, even with currently available methods. In the long term, the availability of a common format for the storage of all interaction datasets should facilitate the thorough exploration and comparison of protein networks (Hermjakob *et al*., 2004). Ultimately, a unified dataset of protein interactions will be constructed for the genome-wide exploration of proteomes.

Short Specialist Review

Investigating protein–protein interactions in multisubunit proteins: the case of eukaryotic RNA polymerases

Benjamin Guglielmi, Cécile Zaros, Pierre Thuriaux and Michel Werner

Service de Biochimie et Génétique Moléculaire, Gif-sur-Yvette, France

The development of protein purification based on fast and nondisruptive affinity purification methods rather than on conventional chromatography has provided growing evidence that many proteins may exist in vast heteromultimeric associations with molecular weights reaching 1 MDa or above (*see* Article 99, **Large complexes by X-ray methods**, Volume 6 and Article 100, **Large complexes and molecular machines by electron microscopy**, Volume 6). Meanwhile, mass spectrometry (*see* Article 7, **Time-of-flight mass spectrometry**, Volume 5) coupled with genome sequence knowledge and to the precise annotation of model organisms such as *Saccharomyces cerevisiae* (*see* Article 43, **Functional genomics in** ***Saccharomyces cerevisiae***, Volume 3, Article 97, **Seven years of yeast microarray analysis**, Volume 4, and Article 39, **The yeast interactome**, Volume 5) has considerably accelerated the identification of polypeptides belonging to such complexes. Thus, the Tandem Affinity Purification method (Rigaut *et al*., 1999), in which two different affinity tags (a calmodulin-binding peptide and *Staphylococcus aureus* protein A) allow the fast purification of multiprotein complexes at near-physiological ionic strengths, preserves structures that are typically disrupted by conventional purification procedures. When applied to the yeast proteome (Gavin *et al*., 2002; Ho *et al*., 2002), this approach suggests that the eukaryotic cell may harbor several hundreds of these complexes (*see* Article 35, **Structural biology of protein complexes**, Volume 5).

Some of these structures have a remarkably stable subunit composition, like the mRNA polyadenylation complex where tandem affinity purification from different polypeptides consistently yielded the same set of 20 different subunits. Others have a much more dynamic organization. Consider, for example, a molecule of DNA-dependent RNA polymerase (Pol) II that successively finds a promoter, passes by an early phase of “abortive” transcription (probably without moving along its DNA), then moves along its template to synthesize RNA in a processive way, and

finally terminates transcription before it possibly recycles onto the same promoter. During these *avatars* of the Transcription Cycle, the same molecule is associated with a nearly 1-MDa Mediator, with the General Transcription Factors TFIIB, TFIIE, TFIIF, TFIIH, with more or less well-defined elongation factors such as TFIIS, Spt4, Spt5, and some others, with the capping enzyme and perhaps with the polyadenylation machine mentioned above (Woychik and Hampsey, 2002). The cumulated mass of this ensemble of more than 70 polypeptides would be close to the size of ribosomes (4.2 MDa in eukaryotes), but it is rather unlikely that a huge "transcriptosome" of that size exists as a stable structure. Indeed, when yeast Pol II subunits were purified by tandem affinity purification, they consistently yielded a 19 polypeptide complex of about 0.75 MDa with the 12-subunit Pol II, the 3-subunit General Transcription Factor TFIIF, two elongation factors (Spt4 and Spt5), and the mRNA cap methylase, which is probably the elongating form of RNA polymerase II. Initiation Factors such as TFIIB, TFIIE, TFIIS, and TFIIH did not copurify with Pol II in tandem affinity purification, although there is good evidence that they *directly* bind Pol II. There was also no trace of the Mediator, although the latter can stably bind Pol II in vitro, thus forming edifices of about 1.5 MDa that can be visualized by electron microscopy.

Knowing the structure of such a huge and more or less transient complex at an atomic level of resolution is undoubtedly one of the most important challenges of modern protein chemistry (*see* Article 99, **Large complexes by X-ray methods**, Volume 6 and Article 100, **Large complexes and molecular machines by electron microscopy**, Volume 6). Short of unforeseen technical breakthroughs, however, this is unlikely to be done rapidly. In the very well studied case of the yeast 12-subunit Pol II complex (Cramer *et al*., 2000; Cramer *et al*., 2001; Armache, 2003; Bushnell, 2003), it took more than 15 years to obtain the (nearly) complete atomic structure of the 12-subunit yeast Pol II, starting from electron microscopic studies that provided the first low-resolution images of RNA polymerases I and II (Edwards *et al*., 1990; Schultz *et al*., 1990). These images paved the way for a very recent atomic reconstitution of Pol II associated with the mononomeric initiation factor TFIIB and elongation factor TFIIS. In most cases, however, cell biologists still largely rely on generic methods for investigating protein complexes in terms of protein–protein interactions and for obtaining at least a broad picture of their general organization. These methods will never replace the precise knowledge brought by crystallographic structures, but are extremely important for obtaining an overall view of the subunit organization of such complexes and of their modular structure.

Protein–protein interaction mapping is based on the idea that individual polypeptides have autonomous folds and that their interactions can therefore be reconstituted when presenting to each other two interacting partners in physiological conditions. The aim, therefore, is to detect the formation of stable heterodimers by suitable biochemical or genetic tests. The biochemical approach is based on protein "pull-down" assays, where one partner polypeptide is fused to an affinity tag (e.g., glutathione-S-transferase or polyhistidine) and bound to a resin (e.g., glutathione Sepharose or Ni-NTA agarose), the putative partner protein being chromatographed through the affinity resin. The retention of a given partner is detected by antibodies directly raised against that partner itself or against suitable epitopes fused to it.

The setup can vary widely. In one form, the binding test is done between two purified proteins. This method is very sensitive but its specificity is questionable since the concentrations of the purified proteins can be in far excess over those that are found in the cell. Indeed, the fact that proteins tend to bind to each other by fairly unspecific interactions is a major source of false-positive. Testing interactions between proteins expressed from whole-cell extracts, typically of *Escherichia coli* or insect viruses (baculoviruses), has the advantage that the protein used as "bait" is challenged for nonspecific interactions by the whole-cell-free extract itself. False-positive interactions are therefore likely to be less frequent, as long as the two partners are not massively overproduced from the host cell.

In the genetic two-hybrid test (Fields and Song, 1989), one polypeptide is typically fused to the Gal4 DNA binding domain (G_{BD}) and tested against putative partners fused to the Gal4 activation domain (G_{AD}). If able to interact, they will form an active heterodimeric Gal4 activator, inducing the transcription of suitable yeast reporter genes in vivo. An interesting development of the two-hybrid method is readily applicable to organisms with compact genomes such as yeast, where it is possible to screen a given bait protein for its ability to interact with a library of small genomic fragments (around 700 bp; Fromont-Racine *et al*., 1997). Since intergenic distances are short and since introns are rare in *S. cerevisiae*, this essentially amounts to testing a random library of coding sequence fragments. In a typical experiment, 10^7 clones can be tested, usually yielding several dozens of interactants. This approach provides an excellent indicator of specificity, as distinct but overlapping fragments corresponding to the same partner should be isolated in the same screen. Comparing the limits of these fragments then allows to rather precisely delineate the interacting domain. This approach has been used to investigate the organization of complex edifices such as the yeast 17-subunit Pol III (Flores *et al*., 1999).

The atomic structure of Pol II, where the 12 subunits are connected by 16 pairwise interactions, offers a rare opportunity for comparing the predictive power of these two approaches and leaves little doubt as to the superiority of the two-hybrid approach, especially when the latter is performed in a library of fragments. GST pull-down assays have been performed with the 12 subunits of the human Pol II, and was also extended to the fission yeast (Kimura and Ishihama, 2000). This can be readily compared to the yeast structural data, since there is considerable homology between the two RNA polymerases and since several of the human subunits can functionally replace their yeast counterparts in vivo. In the human enzyme, the method correctly detected eight interactions, missed eight others, and had seven false-positives (Edwards *et al*., 2002; Figure 1). False-positives were therefore a major problem, especially with some small subunits that were (falsely) predicted to interact with many partners. For example, the Rpb5 subunit interacted with five partners, including Rpb1, in the pull-down experiments, while it only binds the latter in the crystal structure. The *S. pombe* Rpb3 subunit was also seen to interact with six partners, of which only two (Rpb2 and Rpb11) actually did in the structure.

The analysis of yeast RNA polymerase III (Flores *et al*., 1999) suggests that the two-hybrid approach may be much less prone to false-positives. RNA polymerase III is a very complex enzyme that contains no less than 17 subunits (Siaut *et al*.,

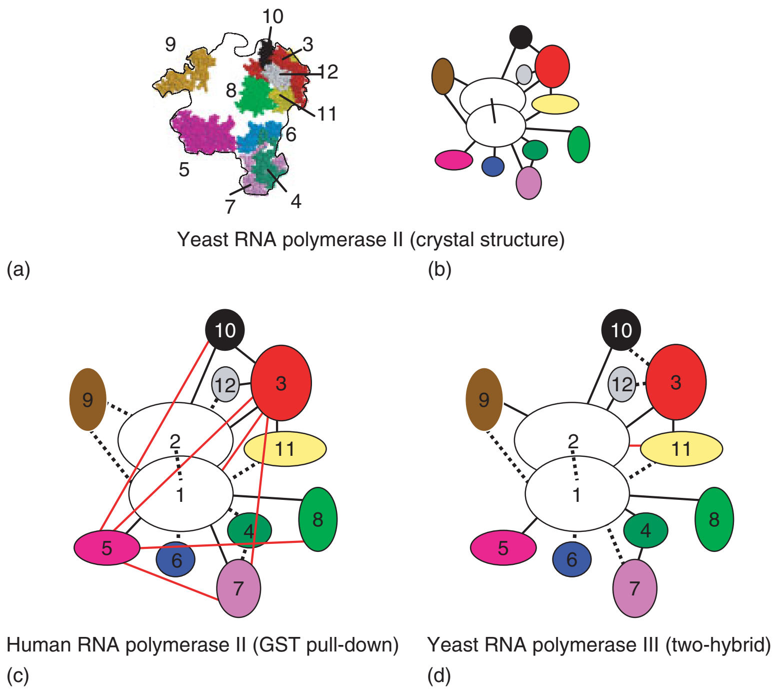

Figure 1 Organization of the subunits in yeast and human RNA polymerases (a) Projection of the RNA polymerase II structure (*S. cerevisiae*). The location of the subunits is indicated within the contour of the model (according to Cramer *et al*., 2000, 2001). Rpb1 and Rpb2 were omitted for clarity. Color code: Rpb3: red; Rpb4: dark green; Rpb5: magenta; Rpb6: blue; Rpb7: violet; Rpb8: light green; Rpb9: orange; Rpb10: black; Rpb11: yellow; Rpb12: gray. (b) Protein interactions in RNA polymerase II, according to the crystallographic analysis (Cramer *et al*., 2000, 2001). The connections between the Pol II subunits are indicated by the black lines. The color code is the same as in (a). (c) Protein interactions in human RNA polymerase II, according to the GST pull-down experiments (Acker *et al*., 1997). The red lines represent false-positive interactions. Dashed lines correspond to interactions that remained undetected. (d) Protein interactions in yeast RNA polymerase III, according to the two-hybrid assay (Flores *et al*., 1999). The code is as in (c)

2003). A core of 12 subunits is homologous (7) or even identical (5) to the 12-subunit crystal structure of Pol II (Armache, 2003; Bushnell, 2003). Nine of the 16 interactions predicted by the Pol II structure were found in the two-hybrid analysis of Pol III, with only one false-positive (Rpb2-Rpb11). Moreover, the domains of interactions predicted by this analysis matched the ones found in the Pol II structure. The five Pol III–specific subunits were also included in this two-hybrid screening, which allocated them to two distinct groups, one formed by the Rpc53 and Rpc37 subunits and one formed by Rpc31, Rpc34, and Rpc82. The case of Rpc37 was quite striking, since this polypeptide was first identified as a specific partner of Rpc53 before being proven to be a bona fide subunit of Pol III (Flores *et al*., 1999). The other three subunits interacted with each other, and are also connected to the 12-subunit core (via a Rpc31-Rpc17 interaction) and to the TFIIIB initiation factor (via Rpc34-Brf1 and Rpc17-Brf1 interactions). Brf1 is a conserved polypeptide that has close homology to the TFIIB initiation factor of Pol

II, and is one of the two polypeptides forming the Pol III initiation factor TFIIIB. The physiological relevance of these interactions was supported by genetic studies where amino acid replacements were selected to impair the two-hybrid interaction and were then shown to result in transcription defects (Andrau *et al*., 1999; Brun *et al*., 1997; Ferri *et al*., 2000) or dissociation of the corresponding subcomplexes (Werner *et al*., 2002). Moreover, the effect of such mutations was in some cases corrected by the overexpression of other components of the same complex (Briand *et al*., 2001).

Most cell biologists would agree that the association of proteins with each other has been a major playground of evolution, improving their biological performance in the extremely crowded environment of living cells. In the eukaryotic cell, one could therefore view the nucleoplasm, the cytosol, and also the matrix compartment of organelles as highly organized communities of multiprotein complexes, rather than as crowded swimming pools for individualistic proteins. However, a long time will pass before structural data provide a general view of how most of these complexes are organized in terms of subunit interactions. In the meantime, there is ample room for generic methods such as the two-hybrid screening approach discussed above and even the somewhat less reliable protein pull-down approach. If carefully applied, these methods can provide important insights into the organization of multiprotein complexes, especially when supported by the in vivo or in vitro analysis of yeast mutants defective in the corresponding protein–protein interactions.

Short Specialist Review

Membrane-anchored protein complexes

Igor Stagljar
University of Zurich-Irchel, Zurich, Switzerland

1. Introduction

The recent advances in analyses of completely sequenced genomes of numerous model organisms, including the human genome, have revealed that approximately one-third of all predicted gene products of a given organism are likely to be associated with membranes (Auerbach *et al*., 2002). These integral and membrane-associated proteins execute a variety of essential cellular tasks. For example, transmembrane receptors bind specific signaling molecules such as hormones, growth factors, and neurotransmitters, and initiate specific cellular responses. Ion channels, transporters, and pumps mediate the exchange of membrane-impermeable molecules between cellular compartments, and between a cell and its extracellular environment. Cell-adhesion molecules enable many animal cells to adhere tightly and specifically with cells of the same or similar type ensuring their segregation into distinct tissues (Fetchko *et al*., 2003). Because of their exposure to the extracellular space, membrane proteins are also of considerable pharmacological importance. Namely, 50% of currently known drug targets (∼500) are either membrane receptors or ion channels. Altogether, the central role of membrane proteins in many cellular processes, their direct link to human disease, and their accessibility toward drugs makes an understanding of membrane protein function desirable.

However, the study of membrane proteins has historically been problematic. The hydrophobic nature of membrane proteins often results in insoluble proteins, which makes protein isolation difficult and therefore hinders the determination of protein complex composition and protein function. Recently, several yeast genetic techniques have made the characterization of interactions among membrane proteins more feasible (Reviewed in (Auerbach *et al*., 2002)). By characterizing protein interactions, researchers can link unknown proteins to proteins of known function, thus providing insight into the unknown protein function. Also, since protein interactions are central in regulating protein activity, knowledge of protein interactions provides understanding of both normal and mutant protein activity.

This review provides a brief overview of the available genetic methods for detecting protein interactions among membrane proteins.

2. Technologies for detecting membrane protein interactions

Generally speaking, the approaches for dissecting protein–protein interactions between membrane proteins can be divided into biochemical and genetic methods (Stagljar, 2003). Biochemical methods establish the state of interacting proteins by directly working with proteins in order to determine the composition of protein complexes, whereas genetic methods indirectly determine protein interactions on the basis of outputs produced through the manipulation of endogenous or exogenous gene networks. Traditionally, biochemical methods such as copurification or coimmunoprecipitation have been used to investigate the composition of protein complexes (Adams *et al*., 2002; Einarson and Orlinich, 2002; Pedrazzi and Stagljar, 2004). However, these methods are tedious and time consuming, requiring extensive optimization for each given protein pair and are therefore unsuitable for the simultaneous application to the tens of thousands of uncharacterized proteins predicted from genome sequences.

Aside from biochemical approaches, expression systems that are based on the detection of protein–protein interactions in vivo have become a popular tool because they require little individual optimization and are well suited for screenings in a high-throughput format. Among genetic assays, the YTH system takes a special position (Fields and Song, 1989). The organism used for the YTH system, the unicellular eukaryote *Saccharomyces cerevisiae*, is well suited to high-throughput screenings, is thoroughly characterized (completely sequenced genome), easy to handle, grows quickly, is well suited for the expression of heterologous proteins, and contains a multitude of selective markers available for nutritional selection (e.g., *HIS3, URA3, TRP1, LEU2*), drug susceptibility (e.g., *URA3*, cyh^{R}), drug resistance (e.g., *kanMX, natMX*), and colors (e.g., LacZ, GFP, GusA) (Melese and Hieter, 2002).

Despite the fact that YTH is a powerful and versatile technique to identify new partners, this method is limited because it cannot be applied to all proteins. For example, since in the YTH system one reconstitutes and monitors TF activity, all assays must be performed within the nucleus. This situation presents a problem when studying membrane proteins, since, in order to evaluate membrane protein interactions by the YTH method, the membrane protein must be portioned into fragments and then relocalized to the nucleus. This limitation not only affects the presentation of the protein of interest, but also limits the protein interacting partners, which can be detected by the YTH system as some membrane proteins cannot be effectively expressed in the nuclear milieu. In addition, membrane proteins are often co- and posttranslationaly modified (they are glycosylated and/or acquire disulfide bridges), and these modifications are not expected to occur in the nucleus (Thaminy and Stagljar, 2002). To overcome these problems, several yeast-based strategies have been designed to study protein interactions in their natural environment – membrane (Stagljar and Fields, 2002).

2.1. G-protein fusion assay

The G-protein fusion assay utilizes the G-protein coupled yeast mating pathway receptor to study protein interactions among membrane proteins (Ehrhard *et al*.,

2000). G-protein coupled receptors are composed of three subunits, G_α, G_β, and G_γ (Figure 1). When the G_α subunit of the G-protein coupled receptor binds a ligand (either mating factor a or α), GTP is exchanged for GDP on G_α, which leads to the dissociation of the trimeric receptor complex into G_α and $G_{\beta\gamma}$. Once the $G_{\beta\gamma}$ subunits are released from G_α, $G_{\beta\gamma}$ is no longer tethered to the membrane, which enables it to act on various downstream effectors thus activating the mating cascade.

In order to detect membrane protein interactions, the yeast-mating pathway G-protein signaling process was modified in the following manner. An unmodified integral membrane protein-Y serves as a "bait" and a "prey" X is fused to the $G_{\beta\gamma}$ subunit of the G-protein coupled receptor ($G_{\beta\gamma}$-X) (Figure 1). In the presence of ligand, if no interaction between $G_{\beta\gamma}$-X and the integral membrane protein Y occurs, the activation of the mating cascade is stimulated and is either detected by an indirect transcriptional readout or by a characteristic cell morphology change, that is, Schmoo formation, induced in the presence of the mating factor ligand (Figure 1b). However, if protein $G_{\beta\gamma}$-X interacts with Y, the Y integral membrane protein continues to sequester $G_{\beta\gamma}$-X at the membrane, which blocks the downstream mating cascade (Figure 1c).

The G-protein fusion assay has been shown to detect known interactions between the binding partners syntaxin 1a and neuronal Sec1 (nSec1), and between the fibroblast-derived growth factor receptor 3 (FGFR3) and SNT-1 (Ehrhard *et al*., 2000). In addition, mutations of nSec1 that fail to bind syntaxin 1a were isolated using the G-protein fusion assay (Ehrhard *et al*., 2000).

2.2. *Reverse Ras recruitment system (reverse RRS)*

In yeast, activation of Ras via the exchange of bound GDP for GTP is mediated by the Cdc25 guanyl exchange factor and results in cell growth. Temperature-sensitive mutations of *cdc25* (allele- *cdc25-2*) grow normally at the permissive temperature of 23°C but fail to grow at the restrictive temperature of 36°C. A constitutively active cytoplasmic version of a mammalian Ras (mRas), which lacks the carboxy-terminal domain "CAAX box" required for normal plasma membrane association, is unable to complement the growth phenotype of the *cdc25-2* allele at 36°C since mRas is not at the plasma membrane (PM). However, if the constitutively active cytoplasmic mRas is associated with the PM via protein–protein interactions, the growth phenotype of the *cdc25-2* mutant yeast at 36°C is complemented. In the reverse RRS, an unmodified integral membrane protein Y "bait" is expressed together with a "prey" protein X fused to mRas (X-mRas) within a *cdc25-2* mutant yeast strain (Hubsman *et al*., 2001) (Figure 2). If Y and X-mRas fail to interact, no growth of *cdc25-2* mutants will be observed at 36°C since X-mRas is not targeted to the PM (Figure 2a). However, if Y and X-mRas interact, X-mRas is recruited to the PM, thus allowing the growth of *cdc25-2* mutant cells at the restrictive temperature of 36°C (Figure 2b).

The reverse RRS has been used to isolate two novel interacting partners of the small GTPase Chp (Hubsman *et al*., 2001). Also, through the use of promoters expressing different levels of the X-mRas prey, Köhler and Müller were able to

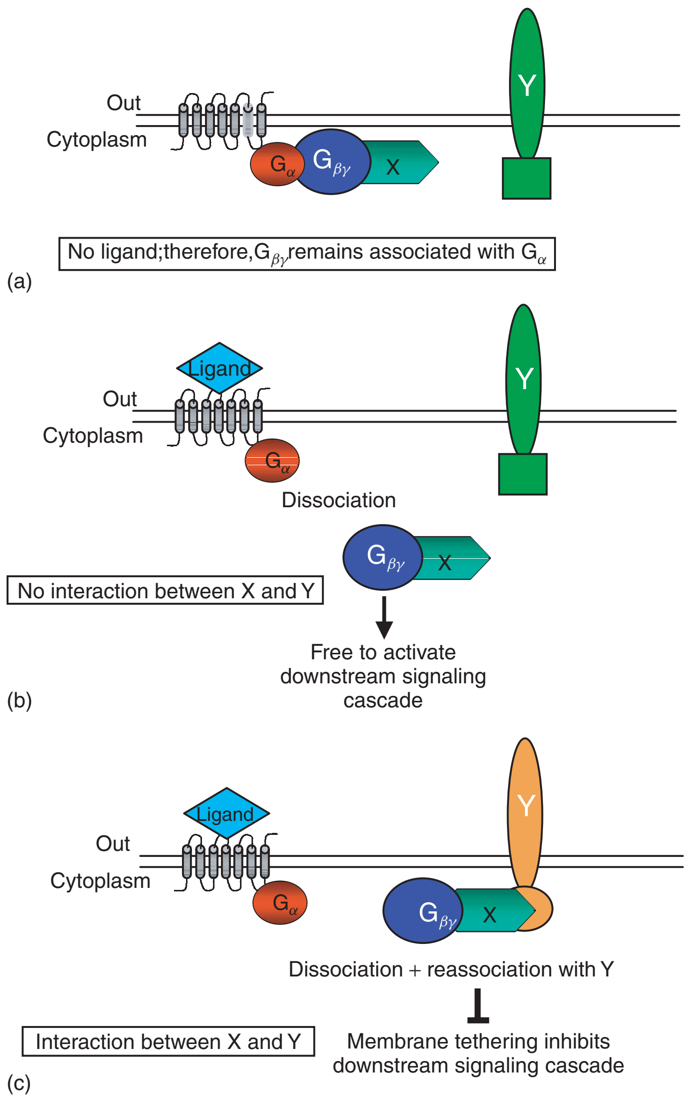

Figure 1 G-protein fusion assay: The G-protein fusion assay can test for interactions between a native integral membrane protein Y and a protein X, which is fused to the $G_{\beta\gamma}$ subunit of the G-protein coupled receptor ($G_{\beta\gamma}$-X). (a) When no ligand is present, the $G_{\beta\gamma}$ subunit of the G-protein coupled receptor ($G_{\beta\gamma}$-X) remains associated with the G_α subunit of the G-protein coupled receptor and no mating cascade events are activated. (b) If no interaction occurs between Y and $G_{\beta\gamma}$-X, upon ligand binding of the receptor, the $G_{\beta\gamma}$-X subunit dissociates from G_α and therefore is free to activate downstream signaling events. (c) If an interaction occurs between Y and $G_{\beta\gamma}$-X, the integral membrane protein Y sequesters $G_{\beta\gamma}$-X at the membrane, which in effect inhibits downstream signaling events although in the presence of ligand

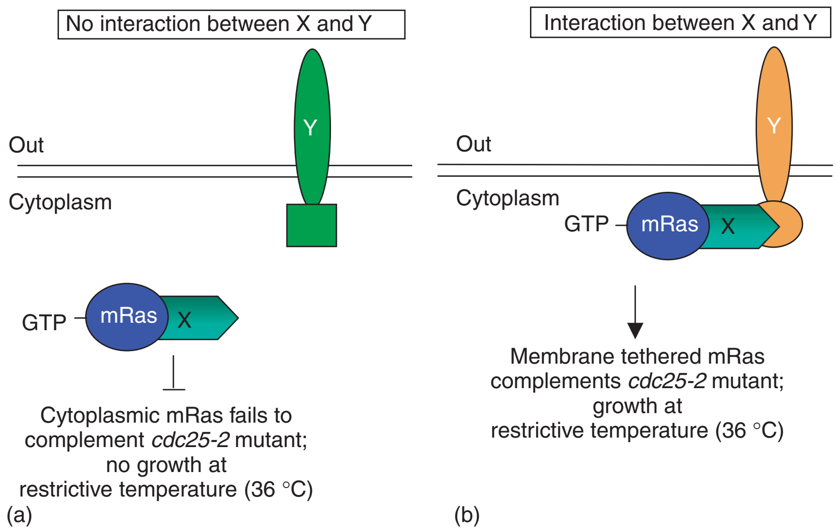

Figure 2 Reverse Ras recruitment system: The Reverse Ras recruitment system tests for interactions between a cytoplasmic constitutively active mRas, which is fused to protein X (X-mRas), and a membrane associated protein Y. (a) If no interaction occurs between proteins X-mRas and Y, protein X-mRas remains cytoplasmic and is unable to complement the growth phenotype of the mutant yeast strain *cdc25-2*. (b) However, if X-mRas and Y interact, X-mRas is then tethered to the membrane, which enables X-mRas to complement the growth phenotype of the mutant yeast strain *cdc25-2*

detect interactions between two membrane-associated proteins (Kohler and Muller, 2003). In this case, high to moderate expression levels of the membrane-associated prey, the adaptor protein growth factor receptor binding protein 2 (Grb2) fused to a myristoylation signal and mRas, supported only slight growth of the *cdc25-2* mutant yeast. Upon addition of an interacting bait, substantial increases in cell growth were observed presumably from the enhancement or stabilization of the X-mRas membrane localization, or perhaps clustering of the Ras facilitated further signaling (Kohler and Muller, 2003). Either way, for certain cases the limitation of using membrane associated proteins as preys, which normally would result in cell growth in the absence of protein interactions, has been eliminated. However, it is still possible that the Grb2 bait used by Köhler and Müller is a special case since Grb2 is a member of the Ras signaling pathway. Furthermore, the question still remains whether the RRS can be used to examine integral membrane proteins as baits.

2.3. Split-ubiquitin assay systems

The split-ubiquitin system provides another approach to study membrane protein interactions (Stagljar *et al*., 1998; Wittke *et al*., 1999). Ubiquitin (Ub) is a small, highly conserved protein that is attached to lysine residues of proteins in order to tag the proteins for proteasomal degradation (Hershko and Ciechanover, 1992). Ubiquitin-tagged proteins are recognized by ubiquitin-specific proteases (UBPs)

that cleave after the C-terminal (Gly 76) residue of Ub and the first residue of the target protein, allowing release of the protein for degradation by the 26 S proteasome. Johnsson and Varshavsky found that native ubiquitin can be split into an N-terminal (Nub) and a C-terminal (Cub) half (Johnsson and Varshavsky, 1994). The two halves retain a basic affinity for each other and spontaneously reassemble to form quasi-native ubiquitin. If a reporter protein is fused to the C-terminus of Cub, it will be cleaved off by UBPs upon assembly of the Nub and Cub moieties (Figure 3a). A point mutation in the N-terminal domain of ubiquitin (NubG) abolishes the affinity of the two halves for each other, such that NubG and Cub fail to refold into split-ubiquitin when coexpressed in yeast (Figure 3b). However, if the two ubiquitin halves are fused to the interacting proteins X and Y, this interaction brings the NubG and Cub moieties close enough together to reconstitute quasi-native Ub, resulting in the release of the reporter protein by the UBPs (Figure 3c).

The versatility of transcriptional activation of reporter genes in yeast was used to convert the split-ubiquitin system into a genetic assay for the in vivo detection of membrane protein interactions (Stagljar *et al*., 1998). In this membrane-based YTH assay (Figure 4), an artificial transcription factor (TF) consisting of the bacterial LexA protein and the *Herpes simplex* VP16 transactivator protein is fused to the Cub moiety. An integral membrane protein (X) is expressed as a fusion to the Cub-LexA-VP16 reporter cassette, with this cassette attached either to the N- or C-terminus of the transmembrane protein, depending on the orientation in the membrane of this protein. The second protein under investigation (Y), either another transmembrane protein or a cytoplasmic protein, is expressed as a fusion to NubG. If interaction between the X and Y proteins occurs, a split-ubiquitin molecule can be reconstituted, leading to the proteolytic release of the transcription factor to activate a reporter gene (Stagljar *et al*., 1998). Thus, the reassociation event initiated by the protein interaction is converted into a transcriptional output that can be easily

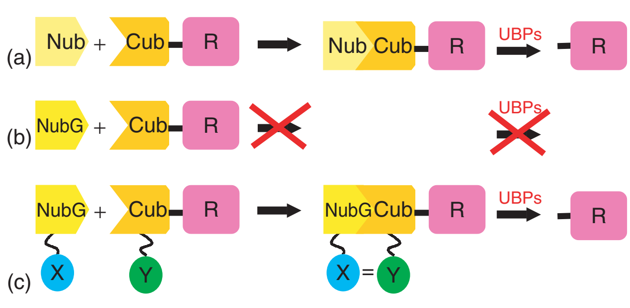

Figure 3 Split-ubiquitin: (a) Ubiquitin can be expressed as an N-terminal (Nub) half as well as a C-terminal (Cub) half that is fused to a reporter protein. The two halves retain affinity for each other and spontaneously reassemble to form the so-called split-ubiquitin. (b) A point mutation in the N-terminal half of ubiquitin (NubG) completely abolishes the affinity of the two halves for each other, and as the separate NubG and Cub parts are not recognized by ubiquitin-specific proteases (UBPs), no detectable cleavage of the attached reporter takes place. (c) NubG and Cub are fused to the interacting proteins X and Y. The X–Y interaction brings the NubG and Cub domains close enough together to reconstitute ubiquitin, resulting in the release of the reporter protein by the action of the UBPs

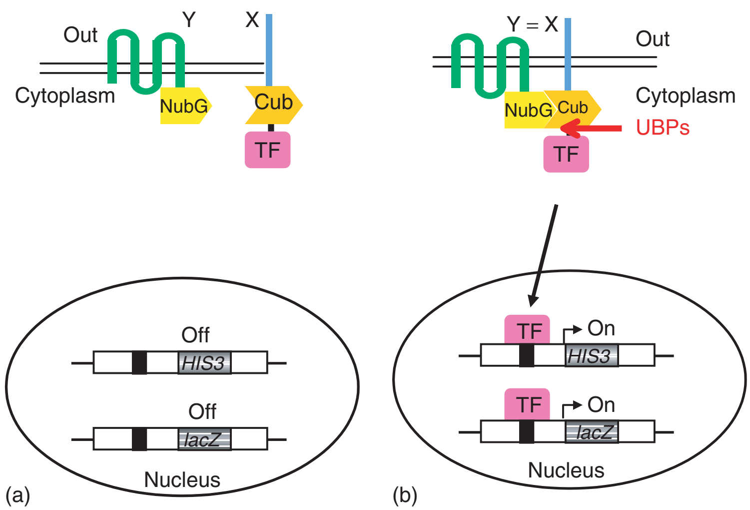

Figure 4 The split-ubiquitin membrane YTH system (MbYTH): (a) A membrane protein of interest X is fused to Cub followed by an artificial transcription factor (TF), while another membrane (or cytoplasmic) protein Y is fused to the NubG domain (Y-NubG). Co-expression of X-Cub-TF with a noninteracting Y-NubG does not lead to the formation of split-ubiquitin nor cleavage by UBPs. (b) On interaction of the X and Y proteins, ubiquitin reconstitution occurs, leading to proteolytic cleavage and the subsequent release of the transcription factor. This factor activates reporter genes to result in cells that are histidine prototrophs and that turn blue in a β-galactosidase assay

detected. This assay has been used to investigate the influence of mutations on the assembly of fragments of presenilin (a protein implicated in the Alzheimer's disease) (Cervantes *et al*., 2001), to characterize the interaction between the yeast α1,2-mannosidase Mns1p and Rer1p (Massaad and Herscovics, 2001) and Wbp1p and Sss1p in the endoplasmic reticulum (Scheper *et al*., 2003), and to study intra- and intermolecular interactions between plant sucrose transporters (Reinders *et al*., 2002). This approach has been successfully adapted for prey library screening and has identified three novel interacting partners of mammalian ErbB3, a receptor tyrosine kinase involved in regulation of proliferation and differentiation of many tissue types (Thaminy *et al*., 2003), and BAP31, a human polytopic integral membrane protein of the endoplasmic reticulum involved in apoptosis (Wang *et al*., 2003). Thus, MbYTH allows rapid and sensitive characterization of proteins associated with a particular full-length transmembrane protein of interest and is generally applicable to most transmembrane signaling proteins.

In another split-ubiquitin-based approach, Johnsson, and colleagues (Wittke *et al*., 1999) have fused a destabilized version of the yeast Ura3 protein, termed rUra3, to the Cub moiety. An integral membrane protein X is expressed as a fusion to the Cub-rUra3 cassette. If cells expressing the fusion protein are grown on a medium containing the compound 5-fluoro-orotic acid (5-FOA), they die because the rUra3 protein converts 5-FOA into a toxic product. However, if the cells coexpress an interacting protein Y fused to NubG, the Cub, and NubG moieties can be forced into close proximity by the X–Y interaction and associate to form

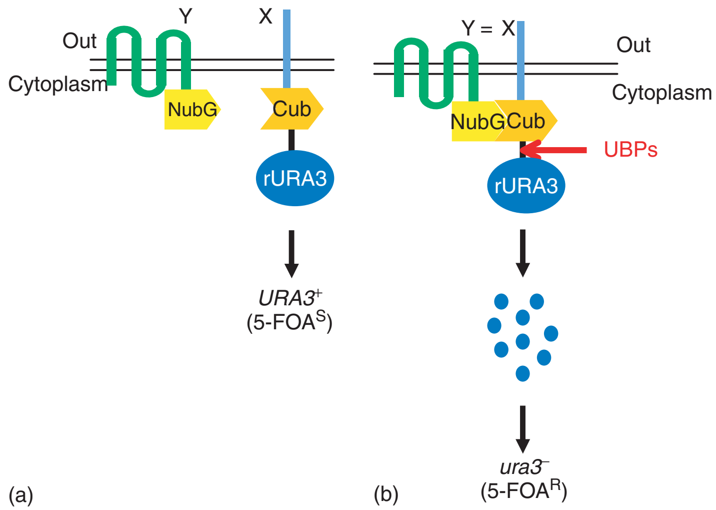

Figure 5 The rUra3-based membrane YTH system: (a) A membrane protein (X) under investigation is expressed as a fusion to the Cub domain, which is fused to a destabilized version of the Ura3 protein (rUra3). The NubG domain is linked to the membrane protein Y. If X and Y do not interact, there is no ubiquitin reconstitution and thus no UBP-mediated cleavage, resulting in yeast cells that contain Ura3 activity and thus die (5-FOA^S) on medium containing 5-fluoro-orotic acid (5-FOA), a toxic metabolite of the Ura3 enzyme. (b) If the X and Y proteins interact, the Cub and NubG domains are brought into close proximity, where they reconstitute an active ubiquitin. Cleavage by UBPs then releases rUra3 from the Cub fusion. The cleaved rUra3 is targeted for rapid destruction by the enzymes of the N-end rule to yield cells that are uracil auxotrophs *(ura3)* and 5-FOA resistant (5-FOA^R)

split-ubiquitin. This association, in turn, leads to UBP-mediated cleavage at the C-terminus of Cub and the release of the rUra3 fusion protein into the cytosol. Since the newly created N-terminal residue of the rUra3 protein is destabilizing in the N-end rule pathway of protein degradation (Varshavsky, 1997), the entire fusion protein is degraded by the 26 S proteasome, leading to cells that can grow on medium containing 5-FOA (Wittke *et al*., 1999). In this way, cells expressing two interacting proteins can be identified by their ability to survive selection on 5-FOA plates (Figure 5). The rUra3-based split-ubiquitin method was used to map the interactions between several *S. cerevisiae* integral membrane proteins (Wittke *et al*., 1999) and to analyze changes in protein conformation and stability of the *S. cerevisiae* protein Sec62, a component of the translocation machinery in the membrane of the endoplasmic reticulum (Raquet *et al*., 2001). In addition, the system has recently been used to systematically test the pairwise interactions between peroxins, proteins that play a role in protein import in the peroxisomes (Eckert and Johnsson, 2003).

3. Conclusions

Membrane-associated proteins perform a critical role in many essential cellular processes and thus represent one of the most important class of drug targets;

currently, they account for ~50% of all known pharmaceutical drug targets. However, analysis of membrane protein interactions is notoriously difficult because of the hydrophobic nature of such proteins, which makes them unsuitable bait candidates to use in most of the interactive proteomic technologies. The development of TAP technology linked to mass spectrometry analyses as well as the YTH system has provided a valuable means to identify proteins that physically interact in vivo (Fields and Sternglanz, 1994; Rigaut *et al*., 1999). Furthermore, in the past four years, the scientific community has witnessed the development of several genetic assays in yeast that are capable of detecting membrane protein interactions (Ehrhard *et al*., 2000; Hubsman *et al*., 2001; Stagljar *et al*., 1998; Urech *et al*., 2003; Wittke *et al*., 1999). In addition, genetic assays based on complementation of proteins or protein fragments have also been developed in organisms other than yeast that allow the monitoring of membrane protein interactions in real time, including ones amenable to use in mammalian cells (Blakely *et al*., 2000; Remy and Michnick, 1999; Rossi *et al*., 1997). Altogether, these assays represent an important step forward toward the elucidation of physical protein–protein interactions, since prior to their development the interactions of membrane proteins were difficult to study using the then existing biochemical and genetic methods. In the near future, a logical extension of the use of various such interactive proteomic technologies for membrane proteins will be their adaptation in a high-throughput format. This approach, in combination with automated screens, should help in elucidating membrane protein interactions on a genome-wide scale. Clearly, such approach will be highly instructive in understanding the pathways underlying many human diseases and will most likely reveal new targets for their therapy. Lastly, such knowledge can be used to provide predictors of certain diseases and may thus be used to develop biomarkers as fingerprints for particular disorders or cellular responses.

Short Specialist Review

Energy transfer–based approaches to study G protein–coupled receptor dimerization and activation

Ralf Jockers and Stefano Marullo
Institut Cochin, Paris, France

Michel Bouvier
Université de Montréal, Montréal, QC, Canada

1. Introduction

Because they play a key role in cell communication, G protein–coupled receptors (GPCRs) constitute a very active area of research and represent the largest group of potential drug targets for medicinal chemistry.

During the past decades, research on GPCRs has taken advantage of several technical advances, the energy transfer–based techniques (ETTs) being one of the most fruitful. These techniques allow the detection of protein–protein interactions and their dynamic variation at "physiological" expression levels in living cells.

ETTs are based on the nonradiative transfer of energy between a donor and an acceptor molecule. Because the efficacy of energy transfer (ET) varies inversely with the 6th power of the distance between the donor and the acceptor, ET from the donor will result in the emission of light by the acceptor only if the two molecules are in close proximity (10–100 Å). The detection of ET between proteins fused to energy donor and acceptor, respectively, is therefore a reflection of molecular interaction between the proteins of interest. A second important parameter, which influences the amount of ET to the acceptor, is its relative orientation to the donor. Accordingly, a variation of ET can also reflect conformational changes within the molecule, to which the donor or the acceptor is appended. Several variants of ET approaches have been used successfully to study GPCR biology. Fluorescence Resonance Energy Transfer (FRET) is the method of choice when the principal aim of the study is to identify the subcellular compartment in which the interaction between two proteins occurs. FRET, between an excited fluorescent donor and a fluorescent acceptor, can be measured with several methods, which have been recently reviewed elsewhere (Eidne *et al*., 2002). Bioluminescence Resonance Energy Transfer (BRET) occurring between luciferase, in the presence

of its substrate, and a fluorescent protein as acceptor is particularly well adapted for high-throughput tests (Boute *et al*., 2002).

2. ETTs to probe GPCR self-association and conformational changes induced by agonists

One of the most striking recent conceptual changes in the field of GPCRs has been the demonstration that these receptors, classically considered to function as monomers, are actually organized as homo- or hetero-oligomers (Table 1) (reviewed in Breitwieser, 2004 and Kroeger *et al*., 2003). Although the precise biological signification of the phenomenon is still a matter of debate, ETTs certainly played a major role in establishing that GPCR oligomerization is constitutive in living cells and that it occurs early in the biosynthetic pathway at “physiological” concentrations of receptors (Ayoub *et al*., 2002; Issafras *et al*., 2002; Terrillon *et al*., 2003). ETTs were also used to identify molecular domains involved in the oligomerization process in intact cells (Overton *et al*., 2003; Salahpour *et al*., 2004) and data obtained with ETTs contributed significantly to a model, which postulates that GPCR homo-oligomerization may be a prerequisite for their targeting from the endoplasmic reticulum to the plasma membrane (Salahpour *et al*., 2004).

A large number of studies have investigated the role of agonist activation on GPCR oligomer formation using ETTs. In most cases, GPCR activation did not result in significant changes of ET, consistent with the notion that constitutive oligomerization is independent of the activation state of the receptor (Ayoub *et al*., 2002). However, in apparent contradiction with the hypothesis above, the activation of some receptors was clearly associated with marked changes of ET (Eidne *et al*., 2002). Although some authors have interpreted these changes as evidence for agonist modulation of dimerization, studies addressing specifically this issue have concluded that agonist-dependent changes in ET most likely reflect internal conformational changes of the receptors (Ayoub *et al*., 2004). The possibility to observe ET changes after agonist challenge may depend on both the amplitude of conformational changes induced by the agonist in a given receptor and on the design of the ET experiment itself.

Conformational changes occurring upon receptor activation were directly probed by FRET experiments in which the donor and the acceptor were inserted at different positions within a single receptor protomer (Vilardaga *et al*., 2003). Different activation and deactivation kinetics of various GPCR (from millisecond to second) were measured in the presence of their agonists or antagonists, and correlations could be established between the timing of the hormonal effects elicited by the receptors and the rapidity of their conformational switch.

3. ETTs to probe signaling events downstream of GPCR activation

During the past several years, ETTs in living cells have challenged some aspects of one of the most solid models in biochemistry, the mechanism of heterotrimeric

G protein activation. Receptor-mediated activation of G proteins was visualized in *Dictyostelium discoideum* by monitoring FRET between the $G\alpha_s$ and the $G\gamma$ subunits fused to energy donor and acceptor fluorescent proteins. According to the established model, receptor stimulation led to a decrease of FRET signal that was

interpreted as evidence for rapid dissociation of the subunits. Surprisingly, however, during continuous stimulation the G_s protein remained in its activated state despite the desensitization of the physiological response, suggesting that whether or not receptors are phosphorylated they catalyze the G protein cycle (Janetopoulos *et al*., 2001). A very similar strategy was followed by a different group, who studied G_i activation by GPCRs in mammalian cells. However, FRET changes were dependent on the specific position of the FRET acceptor on the $G\gamma$ subunit, both agonist-promoted increase and decrease in the signal being observed. This finding led the authors to suggest that the changes in FRET reflected conformational rearrangements of the heterotrimer rather than a true dissociation of the subunits (Bunemann *et al*., 2003). The detection of a persistent G protein heterotrimer during activation clearly questions our understanding of how G proteins propagate signals through either their $G\alpha$ or their $G\beta\gamma$ subunits.

ETTs are particularly well adapted to monitor the translocation dynamics of signaling and/or regulatory proteins to activated receptors. For example, the translocation of ß-arrestins to GPCRs has been monitored by BRET (Angers *et al*., 2000), and was proposed as a tool for the identification of orphan receptor ligands (Bertrand *et al*., 2002). In addition, although the ET-based monitoring of ß-arrestin translocation confirmed a concept that was previously delineated with other approaches, it constitutes a proof of concept of the potential interest of ETTs to investigate the dynamics of protein complex formation throughout GPCR-dependent signaling pathways.

Short Specialist Review

Protein interaction databases

Henning Hermjakob and Rolf Apweiler
European Bioinformatics Institute, Cambridge, UK

Protein interactions occur in many different forms: Proteins interact with and modify each other as elements of signaling chains; they form large molecular machines with more than 100 protein and nonprotein elements, for example, the spliceosome; or, they assemble to provide structural elements of the cell. Proteins interact not only with each other but also with DNA, RNA, and other molecule types. Types of interaction may vary from direct physical contact to very indirect interactions, for example, participation in the same signaling pathway. In many contexts, protein states, in particular, posttranslational modifications, are essential for the function of protein assemblies.

The kind of data produced by experimental technologies to elucidate protein interaction data is similarly diverse, from direct, atom-level structural information by NMR (Pellecchia *et al*., 2002) or X ray via evidence for direct physical contact, for example, by yeast two hybrid assays (Phizicky *et al*., 2003) and information on participation in the same complex by tandem affinity purification (Rigaut *et al*., 1999) to indirect information, for example, colocalization.

With the introduction of technologies for high-throughput interaction screens (Uetz *et al*., 2000; Ito *et al*., 2001; Gavin *et al*., 2002; Ho *et al*., 2002), the number of interactions published in a single publication now varies over four orders of magnitude, from single interactions to more than 20 000 (Giot *et al*., 2003).

The biological and medical importance of protein interactions, high-throughput technologies, and the broadness of data types and experimental technologies have led to the creation of a significant number of protein interaction data collections, from simple HTML tables providing the results of a particular experiment to large databases providing complex tools. We subsequently introduce some criteria for the comparison of protein interaction databases, and describe some major, publicly accessible protein interaction databases on the basis of these criteria (Table 1), focusing on databases for experimentally, not computationally, derived datasets.

Confidence information: High-throughput experiments are often considered less reliable than detailed, low-throughput experiments. To support the user in estimating the reliability of individual interactions, the authors of large-scale interaction data sets often provide quality indications, for example, the grouping into reliability classes (Li *et al*., 2004) or numerical values (Giot *et al*., 2003). In addition, comparative analysis of different interaction data sets provides quality indications. In the simplest case, this is the number of times an interaction has been observed in independent experiments, but quality assessments are also based, for example, on the comparison against a reference data set considered to be correct (von Mering

Table 1 Contents and features of publicly available protein interaction databases

Acronym	BIND	CYGD	DIP	GRID
Name	Biomolecular Interaction Network Database	Comprehensive Yeast Genome Database	Database of Interacting Proteins	General Repository for Interaction Datasets
Description	The Biomolecular Interaction Network Database (BIND) is a collection of records documenting molecular interactions. The contents of BIND include high-throughput data submissions and hand-curated information gathered from the scientific literature.	The MIPS Comprehensive Yeast Genome Database (CYGD) aims to present information on the molecular structure and functional network of the entirely sequenced, well-studied model eukaryote, the budding yeast Saccharomyces cerevisiae.	The DIP database catalogs experimentally determined interactions between proteins. It combines information from a variety of sources to create a single, consistent set of protein–protein interactions.	The GRID is a database of genetic and physical interactions developed in the Tyers Group at the Samuel Lunenfeld Research Institute at Mount Sinai Hospital.
Contents	94 368 interactions (including genetic interactions)	15 488 (9103 physical and 6385 genetic)	44 349 protein interactions	54 000 genetic and protein interactions
Species range	All	*Saccharomyces cerevisiae*	All (107 organisms)	Yeast, Fly, Worm, Human, Mouse, Zebrafish, *S. pombe*, and Rat
Search	Simple search box, and field-specific search interface for complex queries. Search by GI, gene name, PubMed id, protein description. Blast search. Returns 21 interactions for ”lsm7”.	Simple search box. Search by ORF/gene name or PubMed id. Cross-referenced from well-annotated Yeast Genome Database.	Four search forms. Search by description, prosite motif or publication. Blast search. Search by ”lsm7” returned no result, recommended way is to search UniProt, then use the link there, or the sequence.	Simple search box. Search by GI number, ORF/Gene name. Search for ”lsm7” returns 20 interaction partners.
Visualization	Java WebStart application. Network viewer with unusual ”ontoglyphs” to visualize protein properties. Support for Cytoscape in download files.	The CYGD site was being updated at the time of writing, the visualization system could not be accessed.	Graph view with interaction reliability projected on edge colors.	”Osprey” application. Requires local installation, provides powerful graph exploration and integration of user-supplied data. No connection to GRID search, Osprey search only on current dataset.

Confidence information	Indirect, number of PubMed abstracts per interaction.	Not available.	Interaction confidence classification according to three different methods. Grouping of interactions into reliable "core" and less reliable "noncore".	Indirect, list of publications.
Data availability	Free to academic and commercial users.	Free to academic users. License required for commercial use. No redistribution.	Free to academic end users, no redistribution allowed. Flat file download after registration. License required for commercial use.	Free to academic end users, no redistribution allowed. Flat file download after registration. License required for commercial use.
Data structure	Highly detailed, complex data structure. Based on NCBI data types. Published and available from website.	Database structure unpublished.	Relatively simple relational table structure. Overview described in Salwinski *et al*. (2004).	Tab-delimited format.
Download formats	Various full and subset files in ASN.1, Fasta, XML (BIND-specific) format	Tab-delimited files.	XIN (DIP-specific) XML format, PSI-MI XML, Fasta	Tab-delimited format.
Software availability	Mainly C/C++, source code available.	Not available.	Not available.	Not available.
Documentation	Well-documented, including data submission and curation manuals.	Project descriptions.	Usage and search guide documents.	No Grid documentation, but message-based support forum. On-line manual for Osprey.

(*continued overleaf*)

Table 1 (*continued*)

Acronym	HPRD	Hybrigenics	IntAct	MINT
Name	Human Protein Reference Database	Hybrigenics S.A.	Open Source Database of Molecular Interactions	Molecular Interactions Database
Description	The Human Protein Reference Database represents a centralized platform to visually depict and integrate information pertaining to domain architecture, posttranslational modifications, interaction networks, and disease association for each protein in the human proteome.	PIMRider® is Hybrigenics' functional proteomics software platform, dedicated to the exploration of protein pathways. Based on reliable Protein Interaction Maps (PIM®), PIMRider® leads to the unraveling of biological functions.	IntAct provides an open source database and toolkit for the storage, presentation, and analysis of protein interactions. IntAct data is curated from large and small-scale experiments.	MINT is a relational database designed to store interactions between biological molecules. Presently, MINT focuses on experimentally verified protein interactions with special emphasis on proteomes from mammalian organisms.
Contents	15 944 protein interactions	4200 protein interactions	37 680 protein interactions	42 534 interactions
Species range	Human	Human, *Drosophila*, *H. pylori*	All (120 species)	All
Search	Multifield search form. Search by protein name, gene name, posttranslational modification, GO, and domain annotation of proteins.	Simple search box. Search by gene name/description.	Simple search box. Search by gene name, UniProt, InterPro, GO, PubMed, model organism database accession numbers.	Multifield search form. Search by UniProt, InterPro, PDB, GO, PubMed identifiers, gene names, UniProt keywords.
Visualization	Visualization of interacting domains. No graph-oriented visualization.	PIMRider® visualization tool. Java-based for local installation. Graph view, linked to view or interacting domains. Filtering on confidence score (PBS).	Graph visualization, highlighting of graph nodes according to GO annotation.	Java Applet Mint viewer with visualization of number of times an interaction has been observed.
Confidence information	Indirect, by indication of experiment type.	Full integration of PBS score Rain *et al*. (2001)	Indirect, by number of experiments.	Indirect, by number of experiments.

Data availability	Free to academic users. File download after registration. License required for commercial use.	TGF-Beta, Drosophila datasets free for all users after registration. H.pylori dataset free to academic users. File download after registration. License required for commercial use.	Free to academic and commercial users.	File download after registration. No statement on commercial use of redistribution restrictions.
Data structure	Moderately complex, no detail documentation, only autogenerated UML diagram.	Not documented.	Moderately complex, UML diagram and relational schema available on the web.	Data structure follows the PSI-MI standard.
Download formats	HRPD-specific XML format, PSI-MI XML.	PSI-MI XML.	PSI-MI XML, GO formatted controlled vocabularies.	PSI-MI XML.
Software availability	Open source availability announced, but not yet there.	PIMWalker tool (PIMRider with reduced features, but capable of visualizing PSI-MI files) available for noncommercial use after registration. Contains partial source code.	Open source, well-documented and freely available, with installation instructions.	Not available.
Documentation	Extensive FAQ documents.	Compact, but comprehensive PIMRider on-line manual.	Detailed user manual.	On-line documentation.

et al., 2002), shared subcellular location and cellular role annotation of interacting proteins (Sprinzak *et al*., 2003), comparison to RNA expression profiles, or similar interactions in paralogous sequences (Deane *et al*., 2002).

Standards: The number of interactions in the yeast *Saccharomyces cerevisiae* interactome has been estimated to be about 10 000–26 000 (Sprinzak *et al*., 2003; Grigoriev, 2003). Taking into account all relevant species and the change of protein interactions depending on protein and cellular state, the number of interactions is nearly unlimited. As it is unlikely that any given database will be able to collect all available protein interaction data, collecting data from several, potentially specialized databases is essential to assemble a reasonably complete picture of the currently available protein interaction data in a given domain. In addition to providing a complete picture, such collections also provide the basis for interaction data reliability assessments through comparative analysis. However, such collection may be difficult and labor-intensive due to different data formats and annotations used by different databases. To improve this situation, major interaction data providers, among them BIND (Biomolecular Interaction Network Database), DIP (Database of Interacting Proteins), Hybrigenics, HPRD (Human Protein Reference Database), IntAct, MIPS, and MINT, in the framework of the HUPO Proteomics Standards Initiative (**http://psidev.sf.net**) (*see* Article 61, **Data standardization and the HUPO proteomics standards initiative**, Volume 7) have jointly developed the PSI-MI XML format, a community standard for the representation of protein interaction data. PSI-MI 1.0 provides a basic exchange format for protein interaction data (Hermjakob *et al*., 2004a); level 2.0 is under development (Orchard *et al*., 2004) and will provide additional features and an extension to additional molecule types, in particular, RNA and DNA. In addition to a standard format, PSI-MI provides a set of interaction-specific controlled vocabularies to standardize not only the format but also the contents of protein interaction data, for example, to select all data derived by a certain technology.

Visualization: In scientific publications, protein interactions are often visualized as groups of adjacent shapes with textual annotation. While such representations are intuitive, they are difficult to generate automatically. For automatically generated visualization, nearly all tools are based on the abstraction of proteins as nodes and interactions as edges in a graph. This representation allows the application of well-established graph layout algorithms to interaction networks, and provides the basis for additional analysis types, for example, interaction distance, or the identification of clusters of highly interconnected proteins. Although mostly based on this basic abstraction, tools differ significantly in the technical implementation, user interface, and, in particular, in methods to project additional information onto such interaction networks, for example, interaction confidence or Gene Ontology (Harris *et al*., 2004) terms annotated to the interacting proteins. In addition to the tools provided directly by databases, additional tools for graph-based interaction network analysis are provided by commercial and academic organizations, for example, Cytoscape (Shannon *et al*., 2003). Figure 1(a–e) shows the display of lsm7 (yeast) interactions in some visualization systems. Default settings have been used as much as possible.

The basic knowledge about protein interactions is currently increasing at a rapid pace, and a broad array of databases provides large data collections and powerful analysis tools, but the representation of protein interaction facts in near-textbook quality, taking into account interaction details such as protein state and dissociation constants, remains a challenge to the scientific community, both in terms of available tools and available data. Unlike other domains of molecular biology, in particular, DNA and protein sequences as well as macromolecular structures, protein interactions share the problem of data fragmentation in proteomics. Systematic deposition of data in public databases, and exchange of such data between databases, is only emerging. However, the standardization of interaction data through the PSI-MI standard, an increasing collaboration between protein interaction databases, and publicly available, open source analysis tools pave the way to public, user-friendly, and well-accessible protein interaction data resources, reflecting the huge biological significance of protein interactions.

Short Specialist Review

Computational methods for the prediction of protein interaction partners

Alfonso Valencia and David Juan
CNB-CSIC, Protein Design Group, Madrid, Spain

1. Genome- and sequence-based methods

1.1. Phylogenetic profiles

The Phylogenetic profiles method (Pellegrini *et al*., 1999) rests on the very intuitive concept of co-occurrence of related proteins in various genomes. This co-occurrence can be studied by comparing profiles of the YES/NO presence profiles (known as *phylogenetic profiles*) of a given protein pair in a set of complete genomes from/of different organisms (*see* Article 41, **Phylogenetic profiling**, Volume 7 and Article 48, **Connecting genes by comparative genomics**, Volume 7). The basis for assuming a relation between the corresponding proteins grows stronger in direct proportion to the similarity of these profiles. The main advantage of this method is its simplicity, but one of its main drawbacks is the difficulty of distinguishing between functional and speciation/lateral transferences and major speciation events (*see* Article 66, **Methods for detecting horizontal transfer of genes**, Volume 4 and Article 40, **The domains of life and their evolutionary implications**, Volume 7), that is, gram-positive versus gram-negative specific protein-driven profiles. Other problems are related to the method's inability to deal with complex cases such as multidomain proteins, ortholog replacement of a protein by other proteins, or relationships dependent on the organism's environment. However, regardless of the drawbacks and limitations, the idea is still powerful enough to detect interesting sets of potential functional relations.

1.2. Conservation of gene neighboring

This method (Dandekar *et al*., 1998) is based on the well-known organization of bacterial genomes in operons as basic units of transcription coordination of functional-related genes. These organisms tend to cluster in their genomes sets of genes whose expression needs to be concerted. The clearest case is operon

organization. In this method, the order to filter out those cases due to chance conservation of the neighborhood in a number of organisms is translated into statistical evidence of the required functional relation. This method is obviously very powerful in predicting functional links between bacterial genes. However, its validity for eukaryotic organisms remains unclear. Although the relationship established between two genes by this method is fundamentally functional, the strength of this relationship is to point up its usefulness for retrieving sets of potential physically interacting proteins, thus providing an interesting way of drastically reducing the number of proteins to be explored in a particular experiment.

1.3. Gene fusion

Another set of methods focuses on finding out those genes that appear fused in some genome composition (Enright *et al*., 1999; Marcotte *et al*., 1999). The principle is that some organisms have chosen to take advantage of the functional advantages provided by these fusion events, probably related to the organization of protein domains in a single polypeptide. This indicates their potential functional relation. This type of fusion event is apparently more frequent in metabolic proteins (Tsoka and Ouzounis, 2000). An advantage of this method is that it can be applied to eukaryotic genomes, where fusion events in large multidomain proteins are possibly more frequent than in bacterial genomes, even if the extent to which this is true remains still to be quantified. It is also unclear exactly what biological or biochemical advantage is derived from the protein domain fusion.

1.4. Correlated mutations (in silico two hybrid)

This method and the one that follows it (MirrorTree) increase the level of detail in the study of a protein–protein interaction. These two methods use multiple sequence alignments as input information instead of genome composition or organization. Multiple sequence alignments are efficient tools for exploring evolutionary relationships, and they provide a powerful handle on protein evolutionary history.

In the case of the in silico two-hybrid method (Pazos and Valencia, 2002), the relations between a particular pair of proteins are deduced from the detection of correlated mutation changes between the corresponding multiple sequence alignments of these proteins. These interprotein correlated mutations are supposed to be the consequence of coadaptation clues of strong functional relationships and are specifically related to a physical interaction. From a methodological point of view, the signal of correlation is weak, and, in practice, it is difficult to distinguish when/whether/why/how inter- and intraprotein-correlated mutations are detected. Thus, an interaction index is calculated on the basis of the corresponding distributions of possible intra- and interprotein interaction pairs.

1.5. Similarity of phylogenetic trees (MirrorTree)

The second method using multiple sequence alignment information is based on the observed similarity of the gene trees of related proteins (Pazos and Valencia,

2001). This relationship was observed in a number of cases and first quantified by Goh *et al*. (2000). The statistical demonstration of this principle was obtained by analyzing a large set of interacting proteins (Pazos and Valencia, 2001). The interpretation of these observations points to the coevolution of interacting proteins as an important factor in protein evolution that resulted in the detectable similarity of their gene trees. In practice, the method compares the distance matrices of the corresponding sequences instead of the deduced gene trees. These matrices are implicit representations of phylogenetic trees. The similarity between distance matrices is evaluated by using a correlation formulation for the pair of matrices (Pazos and Valencia, 2001).

Both the in silico two-hybrid and the MirrorTree methods use family alignments as a starting point. In both cases, their comparison requires a reduction to sequences of organisms present in both protein families. This reduction enables exploration of the evolution of protein pairs in a comparable framework. However, it also implies a high amount of available sequence information.

Each of these five methods represents a different level of detail in the use of genomic information. The first three of them (phylogenetic profiles, gene neighboring, and gene fusion) work on genes as a whole, exploring global genomic relationships between them (simultaneous presence, genome location, and domain composition). The other two, In silico two-hybrid and MirrorTree, can be classified at a different level of complexity, since they use more detailed information exploring protein sequences and not just whole gene relationships. The increasing level of descriptive detail represents not only some advantages but also some drawbacks. The negative points are related to the reduction of coverage regarding the additional constraints imposed by constructions of the multiple sequence alignments and to the noise introduced by the bias in the distribution of sequences in the corresponding multiple sequence alignments. On the positive side, these methods offer the additional possibility of getting more direct insights into the physical relation between proteins and protein residues, beyond the general functional relations discovered with the genome-based methods.

1.6. From the prediction of interaction partners to the prediction of interacting regions

All these computational methods for the prediction of protein interactions are reasonable alternatives for the prediction of protein interaction partners and a good source of information about the global structure of the interaction network. Together with these general predictions, the problem in molecular biology is how to translate these predictions to the molecular details of the corresponding interactions.

Often, the question of which protein is interacting with a given query protein is followed by questions about the possible region of interaction between the predicted interaction partners. Alternative experimental approaches could be the solution to the structure of the predicted protein complex or the systematic mutagenesis of the potential surface residues (Alanine scanning approach). Of the computational methods described here, those based on structural models, as well as the in silico two-hybrid and MirrorTree methods, provide competitive alternatives. The

in silico two-hybrid and MirrorTree methods have been used for the prediction of interacting surfaces in a number of cases, including preliminary approaches for their combination with physical docking methods (for an overview, *see* Valencia and Pazos, 2003).

1.7. Comparison of genome- and sequence-based method

The first three genome-based methods have been extensively tested against large collections of known proteins extracted from different experimental sources (von Mering *et al*., 2002). In this case, it was clear that the capacity of the computational methods for predicting functional interactions is greater than other methods based on the similarity of expression profiles or experimental yeast-two-hybrid approaches, and only slightly lower than that obtained with biochemical complex pull-down approaches. The analysis of the type of interactions detected by the various experimental and computational methods reveals the specialization of the methods in the detection of interactions with different functions and interaction types (Hoffmann and Valencia, 2003).

We carried out a comparison of the five computational methods on a large set of *Escherichia coli* protein, using the information from 44 fully sequenced bacterial genomes to generate the corresponding family alignments and genome comparisons. The main conclusion of this study is that the five methods have a similar capacity for predicting functional relations in terms of the number of predicting interactions and the accuracy of the predictions. All the methods show the typical sensibility-specificity trade-off, and their coverage is related to their underlying principles. Thus, for example, phylogenetic profiles provide a higher number of interesting predictions than gene fusion (which are less commonly detected). In turn, it includes a larger number of false positives, particularly physical interactions, since its foundation is more closely related to general functional interaction than to physical interaction. This situation is also visible for those methods using multiple sequence alignments, where the increase in specificity in the detection of physical interactions comes with a reduction in the number of predictions.

From these comparative studies, it is clear that the accuracy of the predictions increases when they are validated by more than one method. In the comparative study of the five methods, 37 protein pairs were predicted as interacting by three or more methods and 83.7% of them were found to correspond to proteins of a common biochemical pathway (KEGG and EcoCyc databases) or components of known complexes (DIP database), 56.7% being identified as interacting proteins by automatic exploration of Medline abstracts. These confirmation levels justify the capability of these computational methods to provide reliable predictions, which makes them valuable sources of information that can be combined with high-throughput experimental approaches.

2. Structure-based method

In addition to these sequence- and genome-based prediction methods, a set of alternative approaches uses additional structural information (*see* Article 35, **Structural**

biology of protein complexes, Volume 5). Aloy and Russell (2002) have described a method to derive protein–protein interactions based on homology with complexes of known structure. This method evaluates the probability of homologous complexes by using an empirical interaction potential derived from a known complex. A related approach uses threading (*see* Article 72, **Threading for protein-fold recognition**, Volume 7) to build models of unrelated sequence proteins (Lu *et al*., 2002). In this case, the prediction of interactions is based on the fitness of the protein sequences in the corresponding complexes evaluated with the corresponding threading potentials. In principle, this method aims for a higher sensitivity at the expense of a lower specificity than the homology-based method. In any case, the applicability of these approaches is still limited by the relatively small number of known protein complexes.

2.1. Method based on the statistics of domain composition

Finally, a different set of approaches for the prediction of interactions uses domain composition as the source of information about protein interactions. The first of these methods was developed by Gómez *et al*. (2001), who used the composition of domains of large proteins (the network properties defined by experimentally established protein interactions to assign a probability for each possible interaction) based on attraction/repulsion potentials calculated from known domain–domain interactions, and a global comparison of the structure of the predicted interaction network with the structure of known networks, that is, scale-free structure. A related approach (Sprinzak and Margalit, 2001) represents each protein as a list of descriptive domains (signatures) extracted from the InterPro database of domains. The statistical significance of these signatures is contrasted with a model of distribution of domains in the database.

These domain-composition methods have similar strengths and drawbacks. They are able to provide highly reliable protein interaction predictions, but only for well-known proteins and/or organisms since they depend critically on the availability of high quality and detailed information.

3. Limitations of the computational methods for the prediction of protein interactions

The interesting possibilities opened up by these computational methods should not make us forget their obvious limitations. The interactions extracted by the sequence- and genome-based methods does not directly reflect the complexity of the network of interactions in biological systems (*see* Article 111, **Functional inference from probabilistic protein interaction networks**, Volume 6). The current predictions are still not able to account directly for the distribution of the interactions in space (e.g., subcellular and tissue localization) and in time (e.g., order of the interactions). Just what comprises the relation between the predictions and the nature of the interactions from transient to stable protein interactions also remains unclear. The computational methods are unable to reproduce directly the consequences of

posttranslational modifications in the regulation of protein interactions (e.g., the many interactions specifically controlled by phosphorylation). Finally, the extent to which the computational predictions based on properties of bacterial genomes (such as composition and organization) can be extrapolated to the more complex organization, transcriptional controls, and interactions of eukaryotes is still an open question.

Short Specialist Review

Functional classification of proteins based on protein interaction data

Christine Brun, Anaïs Baudot and Bernard Jacq
CNRS Université de la Méditerranée, Marseille, France

Deciphering gene/protein function on a large scale for a better understanding of cell functioning and organism development is one of the biggest challenges in biology. For this purpose, approaches have been designed following both methodological progress and thinking advancement. In this respect, computational methods played a constant role overtime, evolving with the way biologists were apprehending gene/protein function.

Since the seventies, biologists have been comparing protein sequences using alignment methods (Needleman and Wunsch, 1970; Smith and Waterman, 1981). They progressively introduced useful measures such as the identity and similarity percentages, the z-scores, the Blast scores, and so on (*see* Article 93, **Detecting protein homology using NCBI tools**, Volume 8). Later, methods enabling the comparison of secondary and tertiary protein structures had also been devised (*see* Article 75, **Protein structure comparison**, Volume 7). The main use of such comparison methods is intended to get new insight into protein function by inferring functional relationships between proteins, thereby making possible the inference of function from a protein of known function to a protein of unknown function. The underlying hypothesis upon which such a functional inference is based is the evolutionary conservation of protein sequences and structures in order to perform a conserved function. But the relationship linking sequence, structure, and function is not always straightforward and although these approaches usually lead to useful and testable hypotheses, they remain a risky exercise supporting in some cases wrong conclusions (Devos and Valencia, 2000). For instance, first, a slight change in protein sequence may not be taken into account in the analysis while leading to important functional changes or second, two protein domains with no primary sequence similarity may wrongly be proposed to be functionally unrelated whereas they in fact share the same 3D structure and therefore the same function (Grossman and Laimins, 1996).

In addition, as we previously discussed (Jacq, 2001), the function of a gene/protein is a complex notion that can be defined at several integrated levels of complexity (molecule, cell, tissue, organism levels, etc.). Generally, sequence and structure analyses solely reveal the possible molecular function(s) of proteins when

domains of known function are identified in their sequences. Consequently, the functional knowledge granted by the previously described approaches only concern the biochemical role of proteins, without informing us about the particular cellular, physiological, or developmental process(es) in which it is exerted.

In order to both obtain a more contextual vision of gene/protein function and to be able to make functional predictions, computational methods relying upon genome organization have been developed. The domain fusion or Rosetta Stone method establishes that two proteins from a given organism are functionally related when they exist as a single fused polypeptide in another proteome (Enright *et al*., 1999; Marcotte *et al*., 1999a). Other methods have also been grounded on the facts that genes repeatedly found as neighbours on chromosomes in different organisms may encode functionally related proteins (Pellegrini *et al*., 1999) and that the phylogenetic coinheritance of proteins in several proteomes suggests their functional link (Dandekar *et al*., 1998; Overbeek *et al*., 1999; Tamames *et al*., 1997). Although these methods and their combinations (Marcotte *et al*., 1999b) were used to predict the function for a number of proteins, they still suffer from limitations essentially related to the fact that they work better when applied to completely sequenced genomes and are more appropriate to prokaryotic genome organization compared to the eukaryotic one. In addition, they are only valid for a small number of proteins and solely permit a "functional linkage" to be proposed between proteins sometimes without specifying the cellular process(es) in which the linked proteins are involved.

It then appears that providing new computational methods that enable the decoding of the cellular, the physiological, and the developmental function of gene/proteins on a large scale would not only widen the field of investigations, but more importantly would bring a necessary novel, comprehensive, and integrated understanding of gene function. Because protein action is seldom isolated but rather exerted in concert with other proteins, molecular interactions between proteins are essential actors for all biological processes in all organisms. Having access to the list of protein partners with which any given protein interacts, recapitulates the essential aspects of its cellular function, and it also provides a kind of condensed "functional identity card" for proteins. Interactions thus represent the raw material onto which new methods for protein functional descriptions could be grounded.

Recent years have seen the introduction of many different high-throughput methods, such as the DNA microarrays (*see* Article 90, **Microarrays: an overview**, Volume 4) and large-scale two-hybrid screens. Protein–protein interaction maps are now available for three eukaryotic model organisms: the budding yeast (*see* Article 39, **The yeast interactome**, Volume 5), the worm (*see* Article 38, **The *C. elegans* interactome project**, Volume 5), and the fly (Formstecher *et al*., 2005; Giot *et al*., 2003). They form large intricate networks allowing a renewed vision of the cell functioning as an integrated system. However, they need to be analyzed in detail in order to extract and reveal the functional information they contain. Various methods of biological network analysis have been proposed so far. They may, for instance, allow the identification of functional modules after network clustering (Rives and Galitski, 2003), or assigning a function to proteins of unknown function on the basis of the functional annotations of their neighbors (Vazquez *et al*., 2003).

Another way of analyzing the interaction network is to functionally compare proteins at the cellular level. As stated above, this approach would represent a useful complement to sequence comparison methods, which addresses function at the molecular level. We thus propose a new bioinformatic method named PRODISTIN (Protein distance based on interactions) (Brun *et al*., 2003) and allowing a functional classification of the proteins according to the identity of their interacting partners. The central idea in this interaction-based functional clustering is not to compare proteins themselves but instead to compare the list of their interaction partners, assuming that the more two proteins share interacting partners, the more they should be functionally related. Let us consider three proteins A, B, C, each of them establishing 30 specific interactions (experimentally determined) with other protein partners. If A and C, B and C, and A and B have respectively 25, 13, and 2 common interactors, it seems intuitively reasonable to conclude that A and C are highly functionally related, that B and C share at least some functional features and that A and B are probably not functionally (or only marginally) related. In order to translate this rather simple hypothesis into a mathematical formalism, we decided to calculate the Czekanowski–Dice distance between the proteins forming the network. This distance, which is intended to provide a direct measurement of the functional relationships between proteins (belonging to the same multiprotein complex, the same pathway or more broadly, the same cellular process(es)), corresponds to:

$$D(i, j) = \frac{\#(\mathrm{Int}(i)\Delta\mathrm{Int}(j))}{\#(\mathrm{Int}(i) \cup \mathrm{Int}(j)) + \#(\mathrm{Int}(i) \cap \mathrm{Int}(j))} \tag{1}$$

in which i and j denote two proteins, Int(i) and Int(j) are the lists of their interactors, and Δ the symmetrical difference between the two sets. A key advantage of such a distance is that it increases the weight of the shared interactors by giving more weight to the similarities than to the differences and authorizes the use of a tree representation as an output of functional similarities.

In practice, starting from a list of binary protein–protein interactions (*see* Article 44, **Protein interaction databases**, Volume 5), the PRODISTIN method consists of three different and successive bioinformatic steps: first, the functional distance is calculated between all possible pairs of proteins in the network; second, all distance values are clustered using a neighbor joining algorithm, leading to a classification tree; third, the tree is visualized and subdivided into formal classes. The PRODISTIN classes, which allow a powerful functional interpretation of the tree, are delimited according to tree topology and protein functional annotations (such as Gene Ontology (GO) terms (Ashburner *et al*., 2000)). We define them as subtrees containing at least three proteins sharing the same functional annotations and accounting for at least 50% of the class members.

Figure 1 shows a classification tree containing 602 yeast proteins, result of the application of PRODISTIN to 2946 protein–protein interactions involving 2139 proteins, that is, 38% of the *Saccharomyces cerevisiae* proteome. A detailed analysis of this PRODISTIN tree permitted an integrated analysis of yeast cellular processes and their crosstalks (Brun *et al*., 2003). Indeed, the PRODISTIN method efficiently clusters proteins involved in the same cellular process(es). On the basis of the belonging of a protein to a PRODISTIN class devoted to a particular cellular

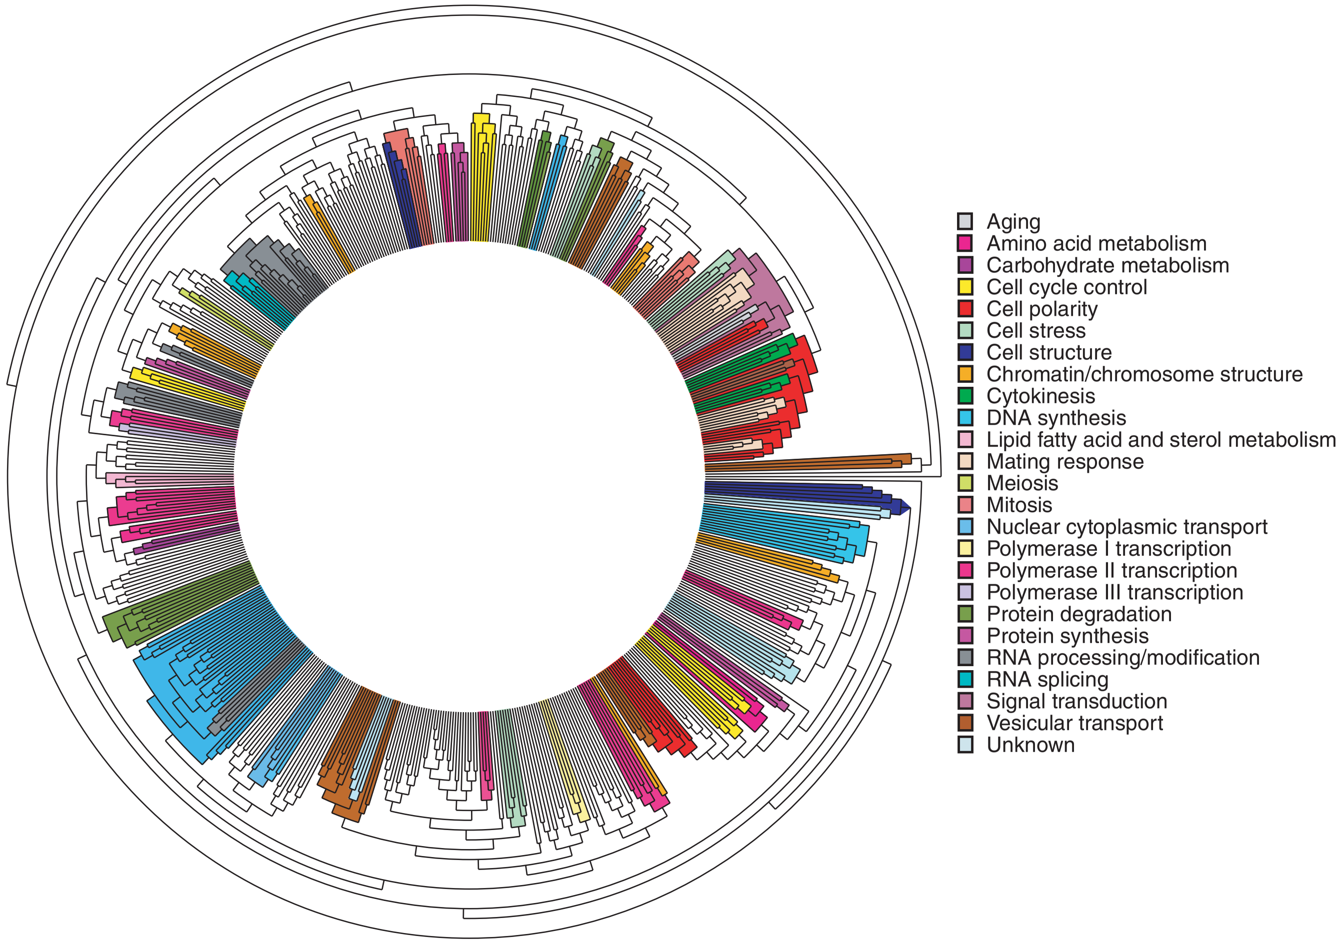

Figure 1 A functional classification tree for 602 yeast proteins computed with the PRODISTIN method. PRODISTIN classes on the circular classification tree have been colored according to their corresponding "cellular role". Protein names have been omitted for clarity

process, the classification enables to propose the involvement of the protein in this process, regardless of the current knowledge about its function. Doing so, we proposed a cellular function for 45% of the otherwise uncharacterized protein present in the tree and the involvement of proteins of known function in other functions (Brun *et al*. 2003).

As predicting the function at a cellular level differs from predicting the function at the molecular level, classifying proteins functionally according to their interaction subnetwork differs from classifying proteins in a structural or a sequence-based manner (*see* Article 82, **Structure comparison and protein structure classifications**, Volume 6, Article 91, **Classification of proteins by sequence signatures**, Volume 6, and Article 92, **Classification of proteins by clustering techniques**, Volume 6). For instance, what should we expect from both types of classification while investigating the evolutionary fate of duplicated genes in yeast? Taking into account that duplicated genes are mainly annotated as having identical molecular function according to GO (Baudot *et al*., 2004), no major differences in classification should be expected using structure- and sequence-based classifications. Conversely, the PRODISTIN functional classification appeared to represent a valuable tool when studying the evolution of the function of the yeast duplicated genes, since a new type of information emerged from its use in an evolutionary perspective (Baudot *et al*., 2004). Indeed, comparing the surrounding subnetwork for paralogous proteins allows us to differentiate several types of paralogue pairs according to their classification features. Three different behaviors of the pairs of paralogues regarding the PRODISTIN classification were identified, leading to the establishment of a scale of functional divergence for the duplicated genes based on the protein–protein network analysis, independently of sequence similarity. From the less to the more divergent in cellular function, either paralogues belong to the same functional class, or to different classes devoted to the same cellular function, or finally to different classes devoted to different functions. Comparing these results with the functional information carried by GO annotations and sequence comparison, it appeared that interaction network analysis reveals functional subtleties, which are not discernible by other means.

As a conclusion, this first use of the functional PRODISTIN classification for yeast proteins in order to address a specific question relative to gene/protein function validates the approach and more broadly, emphasizes the importance of interaction networks data and their analysis in deciphering cell functioning. Considering the cellular function of genes/proteins in the context of a molecular network, as in the aforementioned study of the evolution of the function of duplicated genes, would undoubtedly represent an important issue while approaching several other important biological problems. Just to cite a few, it is likely that questions such as the functional aspects of horizontal transfer, the integration of different signaling pathways or the functional relationship linking orthologous gene/proteins from model organisms for which interaction maps are available will largely benefit from applying the PRODISTIN method. Furthermore, as protein profiling methods will progressively allow a detailed description of the different proteomes from different cell types of the same organism, comparisons of the different protein networks encoded by a single genome will soon become possible. As far as the human proteomes are concerned, it is likely that the new vision of considering diseases

as perturbations of specific molecular networks, which can be studied by network analysis methods such as PRODISTIN will offer new perspectives in understanding both their molecular and their phenotypical aspects.

Short Specialist Review

Analyzing proteomic, genomic and transcriptomic elemental compositions to uncover the intimate evolution of biopolymers

To grow and reproduce, organisms must acquire the constituents of biopolymers from their environments. A number of the elemental constituents of biopolymers, including phosphorus, carbon, hydrogen, nitrogen, and sulfur, are subjected to biogeochemical cycles, and may vary in their abundance in both space and time. Therefore, organisms must be adapted to survive both persistent conditions of their habitats and substantial perturbations in the availability of nutrients. Several studies have now revealed that adaptive biases in the elemental composition of biopolymers may provide one mechanism for dealing with these perturbations. They also demonstrate that nutritional constraints may shape the evolution of biopolymers at a more intimate scale than amino acid (*see* Article 96, **Fundamentals of protein structure and function**, Volume 6) or base composition (*see* Article 47, **The mouse genome sequence**, Volume 3, Article 7, **Genetic signatures of natural selection**, Volume 1). Availability of more and more data on genomes (*see* Article 1, **Eukaryotic genomics**, Volume 3, Article 2, **Genome sequencing of microbial species**, Volume 3, Article 65, **Environmental shotgun sequencing**, Volume 4), proteomes (*see* Article 34, **Large-scale protein annotation**, Volume 7, Article 94, **Expression and localization of proteins in mammalian cells**, Volume 4) and transcriptomes (*see* Article 79, **Technologies for systematic analysis of eukaryotic transcriptomes**, Volume 4, Article 81, **Using ESTs for genome annotation – predicting the transcriptome**, Volume 4) now provides an unprecedented opportunity to study adaptive imprints in the atomic composition of biopolymers, and the factors driving these adaptations.

In their seminal 1989 paper, Mazel and Marlière reported such an imprint in the cyanobacterium *Calothrix* sp. PCC 701 light-harvesting phycobilisome (Mazel and Marlière, 1989). They determined that *Calothrix* expresses a phycobilisome specifically depleted in sulfur-containing amino acids when grown in a sulfur-limited medium. Since phycobilisomes can account for up to 60% of the soluble proteins of cyanobacteria, they proposed that this differential expression allowed a significant sparing in the quantity of sulfur atoms required for protein synthesis. Existence in *Calothrix* of an operon encoding a phycobilisome specifically depleted in sulfur atoms was seen as evidence that nutrient availability could have influenced biopolymer evolution (Mazel and Marlière, 1989).

More recently, a comparable mechanism was reported in the yeast *Saccharomyces cerevisiae* (Fauchon *et al*., 2002). When *S. cerevisiae* is exposed to cadmium, the synthesis of glutathione, a tripeptidic thiol critical for cadmium detoxification, is strongly induced (Vido *et al*., 2001). Fauchon *et al*. revealed that this is accompanied by a deep transcriptional and translational reorganization, leading to the transient expression of a set of proteins containing 30% fewer sulfur atoms than the set expressed in the absence of cadmium. They proposed that this allows significantly more sulfur to be dedicated to glutathione synthesis at a time when it is critical for the cell (Fauchon *et al*., 2002).

In the two above-mentioned examples, biases in atomic composition of subsets of proteins were apparently selected to achieve a significant sparing in an element, at the scale of a whole cell. Other mechanisms could select for biases in the elemental composition of subsets of proteins. For example, Baudouin-Cornu *et al*. (2001) showed that in the yeast *S. cerevisiae*, and the bacterium *Escherichia coli*, proteins used for assimilating sulfur and carbon tend to contain fewer sulfur and carbon atoms, respectively, relative to the rest of the proteomes of these organisms (Baudouin-Cornu *et al*., 2001). The reduced use of an element in a small number of moderately expressed proteins likely has little impact on the overall use of this element by a cell. However, when an element is scarce in the growth medium, amino acids containing this element may be less abundant in the cell, as shown for the two sulfur-containing amino acids in *S. cerevisiae* (Lafaye *et al*., 2005). This would result in a decrease in the corresponding aminoacyl-tRNAs, as observed in the case of amino acid starvations (Dittmar *et al*., 2005), and may reduce the rate of translation of proteins, according to their content of this element. Baudouin-Cornu *et al*. proposed that the biases they reported were selected during transient episodes of scarcity in sulfur or carbon, and allow *S. cerevisiae* and *E. coli* to maintain functional sulfur or carbon assimilatory pathways when their environment is scarce in sulfur or carbon (Baudouin-Cornu *et al*., 2001). Taken together, these studies (Mazel and Marlière, 1989; Baudouin-Cornu *et al*., 2001; Fauchon *et al*., 2002) support the conclusion that systematic biases in the atomic composition of subsets of proteins can result from adaptation to transient changes in the environment.

However, for organisms growing under the normal conditions of their habitat (i.e., in the absence of a severe, transient disruption in nutrient supply), the quantities of different elements required for synthesizing biopolymers are likely influenced by atomic composition of whole genomes, proteomes or total RNA (hereafter, “RNAome”), rather than specific subsets of proteins. Therefore, at this scale, biopolymers may be expected to reflect adaptation to persistent, rather than

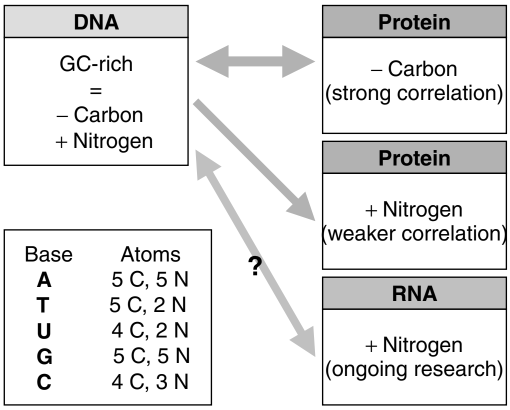

Figure 1 Schematic representation of the relationships between carbon and nitrogen contents of the three main biopolymer classes. The carbon (C) and nitrogen (N) compositions of adenine (A), thymine (T), uracil (U), guanine (G) and cytosine (C) are indicated in the lower left-hand corner. Statistics on the correlations between genomic GC contents and proteomic nitrogen and carbon contents can be found in Baudouin-Cornu *et al*., 2004 and Bragg and Hyder, 2004. See text for more details

transient, environmental features. A small number of studies have now attempted to evaluate the extent of variation among organisms in the elemental composition of biopolymers at the scale of whole genomes and proteomes, and to identify factors (e.g., traits of species) that are associated with this variation.

Analysis of the elemental composition of genomes (double stranded DNA) is straightforward, since genomic carbon and nitrogen content are each related directly to guanine and cytosine (GC) content. Each GC pair has 8 nitrogen atoms and 9 carbon atoms, while each adenine and thymine (AT) pair has 7 nitrogen atoms and 10 carbon atoms. Therefore, a GC-rich genome contains more nitrogen and less carbon per base pair than an AT-rich genome (*see* Figure 1). This observation, taken together with wide variation in GC content among bacteria (ca. 25% to >70%), prompted McEwan *et al*. to test the association between bacterial genomic GC content and the ability to fix atmospheric nitrogen (McEwan *et al*., 1998). They found that within aerobic genera, nitrogen-fixing bacteria had higher genomic GC content, and therefore higher genomic nitrogen content per base pair, than nonfixing species (McEwan *et al*., 1998). They suggested that this may represent an adaptive association between nitrogen expenditure in genomes (and potentially in RNAomes, see below), and nitrogen fixing. However, different types of biopolymers are represented in different abundances and may therefore have different consequences for nutrient use. According to Neidhardt and Umbarger's compilation, 3% of the dry weight of a bacterial cell is accounted for by DNA, 55% by proteins, and 20% by RNA (Neidhardt and Umbarger, 1996). Therefore, in terms of nutritional constraints, the elemental composition of genomes may be less important than the elemental composition of proteomes or RNAomes.

Predictions of proteomes from genome sequences (*see* Article 16, **Searching for genes and biologically related signals in DNA sequences**, Volume 7, Article 25, **Gene finding using multiple related species: a classification**

approach, Volume 7), have allowed interesting insights into proteome elemental compositions of unicellular organisms, especially prokaryotes (*see* Article 13, **Prokaryotic gene identification *in silico***, Volume 7). For example, Bragg and Hyder found that proteome nitrogen and carbon content were correlated positively and negatively (respectively) with genome GC content. This means that the carbon and nitrogen contents of genomes are correlated positively with the carbon and nitrogen contents of proteomes, respectively (Bragg and Hyder, 2004). These correlations are due to the structure of the genetic code (Baudouin-Cornu *et al*., 2004; Bragg and Hyder, 2004). Additionally, predicted whole proteomes allow more subtle studies of proteomic elemental composition than just the comparison of means. Using the quantile representation proposed by Karlin *et al*. to compare amino acid compositions (Karlin *et al*., 1992), Baudouin-Cornu *et al*. found the same negative correlation between genome GC contents and proteome carbon contents, but also showed that the quantile distributions of proteome carbon contents were stochastically ordered, whereas quantile distributions of proteome nitrogen contents were not (Baudouin-Cornu *et al*., 2004). This suggests that mean values of proteomic carbon content likely provide a reliable indication of relative proteomic carbon use among species, whereas for nitrogen, mean proteomic values are less likely to provide a reliable indication of relative proteomic nitrogen use. That is, the expression levels of proteins with different nitrogen content (within proteomes) may have a relatively larger role in determining average protein nitrogen use among organisms (e.g., in comparison to carbon). This highlights the potential usefulness of considering protein expression levels explicitly in studies of proteomic elemental composition, as expression data become increasingly available.

Although both studies of proteomic carbon and nitrogen composition led to interesting observations (Baudouin-Cornu *et al*., 2004; Bragg and Hyder, 2004), they did not identify links between the elemental composition of proteomes and the environments in which different organisms live. A recent study of proteome sulfur contents has revealed such relationships (Bragg *et al*., in press). In particular, we observed a tendency for species living at high temperature to have lower proteomic sulfur use. To our knowledge, this is the first example of a simple relationship between an environmental feature and the quantity of a specific element used in proteins, at the level of whole proteomes. However, as genome sequences and lifestyle data become available for a growing number of microorganisms, we anticipate that more relationships will be revealed between environmental factors and the atomic composition of proteomes or RNAomes.

Variation in the nitrogen and carbon content of RNAomes among organisms has not (to our knowledge) been considered explicitly, despite the observation that RNAs may account for 20% of cellular dry mass (Neidhardt and Umbarger, 1996). The bases of RNA, A, C, G, and U (uracil), contain 5, 3, 5, and 2 nitrogen atoms, respectively, while A and G each contain 5 carbon atoms, and C and U each contain 4 carbon atoms. The nitrogen and carbon content of RNAomes are not related exactly to GC content (as in genomes), because (1) RNAs in cells are typically single-stranded, and (2) different RNA molecules may vary greatly in their abundance. However, if the parity G = C and A = U holds approximately (Chargaff's second parity rule, see Forsdyke and Mortimer (2000) for a review), and GC-rich genomes encode GC-rich RNAomes, it is likely that organisms with high

genomic nitrogen content (high GC content), would have nitrogen rich RNAomes (McEwan *et al*., 1998). This suggests that there is a correlation among organisms from relatively low nitrogen content in the three main biopolymers (and low GC content), to relatively high nitrogen content (and high GC content) in these biopolymers (Figure 1). This prediction hints that comparing RNAome elemental composition among species would reveal interesting features and deserves to be undertaken. In particular, ribosomal RNAs (rRNAs) constitute up to 80% of the total RNAs in a cell, and may therefore have an inordinate influence in the elemental composition of total RNA. An analysis of the elemental composition of rRNA sequences among different organisms may thus provide useful insights into variation in nitrogen expenditure in RNA.

Future studies of the atomic composition of biopolymers hold much promise for our understanding of both biopolymer evolution, and the nutrient requirements of organisms. Such studies should continue to examine variation in atomic composition both among subsets of biopolymers within organisms, and among organisms. For example, they might include analyses aimed at testing whether multicellular organisms have biases in the atomic composition of biopolymers that are expressed during specific stages of development, or in specific types of cells. Among organisms, it may be enlightening to study the atomic composition of biopolymers by testing hypotheses concerning traits that influence the access of different organisms to specific nutrients.

Short Specialist Review

Topology of protein interaction networks and cell physiology

Marie-Claude Marsolier-Kergoat
Service de Biochimie et de Génétique Moléculaire, CEA/Saclay, Gif-sur-Yvette, France

Cell physiology involves physical interactions between many types of molecules. The protein interaction network of a cell can be defined as the set of the nonoriented links connecting proteins (the network vertices) that have been experimentally found to interact. The accumulation of small-scale studies and the development of high-throughput technologies have recently led to a first description of these networks in several organisms like the bacteria *Helicobacter pylori* (Rain *et al*., 2001) and *Escherichia coli* (Butland *et al*., 2005), the yeast *Saccharomyces cerevisiae* (Uetz *et al*., 2000; Ito *et al*., 2001; Gavin *et al*., 2002; Ho *et al*., 2002) (*see* Article 39, **The yeast interactome**, Volume 5), and the metazoans *Drosophila melanogaster* (Giot *et al*., 2003; Formstecher *et al*., 2005) and *Caenorhabditis elegans* (Li *et al*., 2004) (*see* Article 38, **The *C. elegans* interactome project**, Volume 5). Numerous analyses have reported the existence of correlations between topological characteristics of proteins in the interaction networks and their evolutionary conservation or other functional features (Jeong *et al*., 2001; Fraser *et al*., 2002, 2003; Maslov and Sneppen 2002; Barabasi and Oltvai, 2004). However, these correlations have remained largely controversial. Thus, the potential correlation between the number of links (or degree) of a protein and its evolutionary rate, initially reported by Fraser and collaborators (Fraser *et al*., 2002, 2003), has been subsequently questioned by several reanalyses (Bloom and Adami, 2003; Jordan *et al*., 2003; Hahn *et al*., 2004), one of them suggesting that this correlation is a mere artifact resulting from the effect of protein abundance (Bloom and Adami, 2003). In this article, I will address two related questions: Locally, are the topological characteristics of a protein correlated with a basic, functional feature like its essentiality? Globally, can the overall structure of protein interaction networks be interpreted in terms of cell physiology? Another article in this section deals with the prediction of gene function and biochemical networks from protein interactions (*see* Article 37, **Inferring gene function and biochemical networks from protein interactions**, Volume 5) and complements this approach.

1. Correlations between the essentiality of a protein and its topological characteristics in interaction networks

A protein is called essential when the deletion of the corresponding gene is lethal even under optimal growth conditions. Protein essentiality has so far only been

systematically assessed in *S. cerevisiae* (Giaever *et al*., 2002) and in *C. elegans* (Kamath *et al*., 2003), and the discussion about the correlations between protein essentiality and protein network topology has been mostly restricted to *S. cerevisiae* due to the wealth of available data for this model organism. It was quickly pointed out that protein interaction networks, like many other biological, technical or social networks, exhibit high variability in their vertex degree and consist of a majority of low-connected vertices and a minority of highly connected ones (Jeong *et al*., 2001). The degree distribution of the protein interaction networks was originally claimed to follow a power law (Jeong *et al*., 2001). However, subsequent studies have shown that this conclusion was not justified (Przulj *et al*., 2004; Tanaka *et al*., 2005; see also Keller, 2005), so that it appears more appropriate to simply describe the protein network degree distribution as large. Networks with a large degree distribution are characterized by the fact that their structure (as assessed by the size of their largest cluster of vertices or by their diameter, the average length of the shortest paths between any two vertices) is little affected by random vertex removal but highly sensitive to the removal of their most connected vertices (Albert *et al*., 2000). Equating gene deletion to vertex removal and lethality to network failure allowed to propose that the minority of highly connected vertices in a protein interaction network should correspond to essential proteins. This suggestion was initially made by Barabasi and collaborators (Jeong *et al*., 2001), and since then others have striven to demonstrate a correlation between the essentiality of a protein and its degree in interaction networks (Wuchty, 2004; Yu *et al*., 2004, for a review see Barabasi and Oltvai, 2004). However, we have shown that this correlation is mainly due to biases in the protein interaction databases (*see* Article 44, **Protein interaction databases**, Volume 5) used by these authors (Coulomb *et al*., 2005). Among other things we have demonstrated that, for *S. cerevisiae*, essential proteins are the objects of almost twice as many research articles than nonessential ones and we have found the predictable positive correlation between the number of articles referring to a protein and the number of its interactants indicated in databases like Database of Interacting Proteins (DIP, Xenarios *et al*., 2000) that record the results of small-scale studies (Coulomb *et al*., 2005 and unpublished data). Analysis of an a priori unbiased data set of yeast protein interactions yielded at best a marginal correlation between protein degree and essentiality (Coulomb *et al*., 2005). Similar results (unpublished data) have also been found using data from systematic studies on *C. elegans* (Kamath *et al*., 2003; Li *et al*., 2004). Other correlations have also been reported between the essentiality of a protein and the average degree of its neighbors or its clustering coefficient (the ratio between the number of links connecting the k neighbors of a given vertex and $k(k-1)/2$, the number of all possible links between these k neighbors) (Maslov and Sneppen, 2002; Yu *et al*., 2004). However, we failed to observe these correlations using different, a priori unbiased databases (Coulomb *et al*., 2005).

2. Overall structure of protein interaction networks and cell physiology

The large degree distribution of protein interaction networks has been suggested to account for cell robustness against mutation (Jeong *et al*., 2001; Barabasi

and Oltvai, 2004). The hypothesis that only the removal of highly connected proteins is lethal would have elegantly explained the fact that only 18.7% of *S. cerevisiae* proteins are essential (Giaever *et al*., 2002). However, this hypothesis is inconsistent with the observation that the essentiality of a protein is poorly, if ever, related to its degree in interaction networks.

Negative degree correlation, that is a propensity for high-degree vertices to attach to low-degree vertices, was another global feature reported for protein interaction networks and proposed to have a physiological signification (Maslov and Sneppen, 2002; Newman 2002; 2003). The systematic suppression of links between highly connected vertices was suggested to decrease the probability of cross-talk between different functional pathways and to increase mutational robustness (Maslov and Sneppen, 2002). However, we and others found that this degree correlation was assessed using severely flawed data sets derived from two-hybrid experiments (Aloy and Russell 2002; Coulomb *et al*., 2005), and using a priori unbiased databases failed to reveal any positive or negative degree correlation in protein networks (Coulomb *et al*., 2005).

3. Conclusion

General connections between the topology of protein interaction networks and cell physiology are thus difficult to point out. The local, topological characteristics of proteins are at most weakly related to their essentiality and the global features of protein interaction networks, like their large distribution of degrees or their lack of degree correlation, do not lend themselves to obvious physiological interpretation. The phenomena that determine the structure of protein networks thus remain debated. It has been shown that many structural characteristics of experimentally observed coexpression and interaction networks could be generated with standard evolution processes involving gene duplication and addition and deletion of links (Wagner, 2003; Amoutzias *et al*., 2004; van Noort *et al*., 2004), which suggests that the structure of these networks could simply be determined by construction processes. Alternatively, Shakhnovich and coworkers have studied a physical model of protein interaction strictly based on desolvation (nonspecific interactions) and have shown that the networks constituted by these connections devoid of biological signification exhibit many of the structural characteristics of the experimentally determined protein interaction networks (Deeds *et al*., 2006). So, besides their physiological interpretation, even the very structure of protein interaction networks remains a puzzling question.

Bioluminescence resonance energy transfer

Ralf Jockers and Stefano Marullo
Institut Cochin, Paris, France

1. Introduction

The elucidation of complex networks of interaction among proteins is one of the most important and challenging tasks of postgenomic biology. Among the available approaches to study protein–protein interaction in living cells, Resonance Energy Transfer (RET)-based techniques have become increasingly popular over the past few years. RET consists of nonirradiative energy transfer (ET) between a donor and an acceptor. Because the efficacy of ET varies inversely with the 6th power of the distance between the donor and acceptor molecules, ET from the donor results in the emission of light by the acceptor only if the two molecules are in close proximity (10–100 Å). Therefore, the detection of ET between two proteins fused, respectively, to an energy donor and an acceptor, often reflects the existence of molecular interaction between the proteins of interest. In contrast, the lack of RET does not exclude the possibility of interaction between two proteins, for example, when the conformations of the two interacting partners keep the acceptor too distant from the donor. A second important parameter, which may hamper the amount of ET from donor to acceptor, is the relative orientation of the donor to acceptor molecules.

Among existing RET approaches, Fluorescence Resonance Energy Transfer (FRET) is the method of choice when the principal aim of the study is to identify the subcellular compartment where the interaction between two proteins occurs. In FRET experiments, the cyan variant (CFP) of the green fluorescent GFP and its yellow variant (YFP) are widely used as energy donor and acceptor, respectively. Other combinations of fluorescent proteins are possible, such as GFP together with fluorescent proteins emitting in the red part of the spectrum. Various approaches to measure FRET exist and have been compared in recent reviews (Jares-Erijman and Jovin, 2003). They all require the external excitation of the donor molecule.

In 1999, a novel ET technique, the Bioluminescence Resonance Energy Transfer (BRET), has been developed (Xu *et al*., 1999), on the basis of a slightly different principle inspired by a natural phenomenon observed in glowing marine organisms. In the presence of its substrate, coelenterazine, *Renilla* luciferase (Rluc, the luminescent energy donor) transfers some energy to a GFP variant (the energy

acceptor). No excitation of the donor is required in this case and the substrate, which is membrane permeable, can be added to the supernatant of cultured cells. Various types of coelenterazines have been developed, which are characterized by different emission wavelengths and intensities as well as by the duration of the light emission. Two main acceptor fluorescent proteins are used in BRET experiments, the YFP and a blue-shifted fluorescent protein (GFP2). Each acceptor works with a different coelenterazine emitting at specific wavelengths.

BRET protocols have been designed to monitor and quantify both constitutive and regulated molecular interactions in intact cells. A practical guideline on how to perform BRET experiments has been published recently (Issad and Jockers, 2005). Here we will discuss the advantages and limits of BRET-based techniques and illustrate possible applications by describing some specific assays.

2. Strengths and weaknesses of BRET-based assays

BRET is a technique of choice for many applications in cell biology and molecular pharmacology to study constitutive and regulated interactions as well as the dynamics of intra- and intermolecular conformational changes. The experimental conditions for BRET assays are very flexible since the experiments can be performed with purified proteins, subcellular fractions, and permeabilized or intact cells. The opportunity of using intact cells limits the number of false-positive interactions, which can be observed in assays where the integrity of subcellular compartments is lost. Moreover, compared to the yeast two-hybrid system, BRET can be performed in mammalian cells in which the native subcellular localization and posttranslational modifications of the interacting partners are preserved. BRET values are reliable since the measured signals correspond to average values reflecting variable concentrations of interacting partners in large cell populations. As detailed below, BRET saturation experiments may provide quantitative data on the propensity of two interacting partners to interact with each other. Finally, another important feature of BRET assays is the possibility to quantify the amount of expressed energy donor and energy acceptor independently in each individual experiment. This control is important to differentiate specific BRET signals from artificial interactions caused by overexpression of the proteins of interest used in the assay.

Cell autofluorescence and photobleaching, which may cause problems in FRET assays, are minimized in BRET experiments, since the excitation of the energy donor is not obtained through external irradiation. On average, the BRET assays have been estimated to be approximately 10 times more sensitive than the FRET assays in a microplate format (Arai, Ueda *et al*., 2000; Arai *et al*., 2001).

Although BRET measurements require instrumentation with specific features, several BRET readers are now available from different suppliers. BRET readers must be capable of measuring emitted light quasi-simultaneously at two different wavelengths. In addition, these readers are generally driven by a software that calculates BRET ratios in real time. The experimental setup is easy and fully compatible with measurements in 96- or 384-well microplates, permitting to test multiple different experimental conditions very rapidly. Therefore, BRET assays

are equally well suited for academic research and companies, which need to develop high-throughput tests, for drug screening (Boute *et al*., 2002).

Despite all the advantages listed above, some limitations of the BRET technique exist nevertheless. Wild-type proteins cannot be used in BRET assays, as the fusion to a donor or to an acceptor is an inherent feature of the approach. Consequently, the biological properties of fusion proteins should be tested carefully and compared to the wild-type counterpart to be sure that function and/or subcellular localization is not markedly modified. Fusion proteins need to be expressed in heterologous models, which may be difficult to obtain in some cases, although modern transfection reagents and viral vectors allow heterologous protein expression in almost any cell type. Some chemicals may inhibit luciferase activity, whereas others may quench the BRET signal, owing to strong absorption between 400 and 600 nm. Pilot experiments should be performed to detect potential interferences in the assay buffer. Despite several successful attempts of BRET measurements on subcellular fractions obtained by cell fractionation, a suitable microscope-associated detection system has not been developed so far to directly visualize the subcellular localization of BRET in living cells. The limiting factor for achieving this goal is the low intensity of the light generated by the *Renilla* luciferase. Therefore, the development of more sensitive light detectors is necessary to overcome this limitation. Thus, FRET remains, so far, the method of choice when the principal aim of the study is to identify the subcellular compartment in which the interaction between two proteins occurs.

3. Applications of BRET

Protein oligomerization and the regulated movement of proteins between two compartments in living cells have been extensively investigated using different approaches including BRET; they will be discussed in more detail to illustrate the different facets of BRET assays.

3.1. Monitoring protein oligomerization by BRET

The biotechnological use of BRET was first described by Xu *et al*. (1999) who studied the dimerization of bacterial transcription factors of the Kai B family involved in the regulation of the circadian rhythm. Subsequently, BRET has been widely used to study the oligomerization of membrane proteins, in particular, G protein–coupled receptors (GPCR) (reviewed in Kroeger and Eidne, 2004). The BRET approach provided a significant input in the demonstration that constitutive receptor homo-oligomers of GPCRs exist in living cells at physiological receptor expression levels (Issafras *et al*., 2002). Recently, more sophisticated quantitative BRET assays have been developed in order to quantify the relative abundance of receptor oligomers versus monomers, to determine the relative affinity between different protomers engaged in the formation of homo- and heterodimers and to interpret agonist-induced changes in BRET signals (Ayoub *et al*., 2002; Mercier, *et al*., 2002; Couturier and Jockers, 2003). Although these quantitative assays

have been mostly developed to study GPCR oligomerization, the method may be extrapolated to any type of protein that can potentially undergo oligomerization.

The most popular quantitative assay developed so far is the BRET donor saturation assay (Mercier *et al*., 2002; Couturier and Jockers, 2003). Several independent transfections are performed with a constant amount of BRET donor and increasing quantities of BRET acceptor. As the amount of acceptor increases, the BRET signal rises as a hyperbolic function and reaches an asymptote ($BRET_{max}$), which corresponds to the saturation of all available donor molecules by acceptor molecules. Assuming that the association of the fusion proteins occurs at the equilibrium, the amount of acceptor required to achieve half-maximal BRET ($BRET_{50}$), for a given amount of donor, reflects the relative affinity of the two partners. The relative affinities of several interaction partners have been determined using this method, which allowed to compare the propensity of receptor isoforms to be engaged in homodimers versus heterodimers (Mercier *et al*., 2002; Terrillon *et al*., 2003; Ayoub *et al*., 2004; Breit *et al*., 2004; Ramsay *et al*., 2004).

Quantitative assays may be used in some cases to estimate the proportion of the dimeric versus monomeric fraction of a protein (Ayoub *et al*., 2002; Mercier *et al*., 2002; Couturier and Jockers, 2003). If a free equilibrium governs the association of the monomers, whether they are fused to the BRET donor or to the acceptor, one can predict that in the case of a 1:1 molecular ratio of the two BRET partners, 50% of formed dimers (those containing one donor and one acceptor) would produce BRET, whereas dimers that contain only BRET donors or acceptors, would each represent 25% of total dimers. Accordingly, if the proteins of interest only exist as dimers under these conditions, the expected BRET value should correspond approximately to the $BRET_{50}$, which is 50% of the maximal BRET value ($BRET_{max}$), the value reached upon complete saturation of the BRET donor by the acceptor. If the observed BRET value falls significantly below 50% of the $BRET_{max}$, the hypothesis above is not confirmed and a significant proportion of free monomers is likely present. This type of experiment requires that a precise quantitation of BRET partners is available, for example, using binding assays, which correlate fluorescence and luminescence values with real concentrations of BRET partners.

BRET donor saturation assays also proved to be useful for the interpretation of the BRET signal changes induced by agonists (Couturier and Jockers, 2003; Lacasa *et al*., 2005; Percherancier *et al*., 2005). As mentioned above, BRET efficacy varies with both the distance between the donor and the acceptor and the relative orientation of the acceptor to the donor. Consequently, a change of BRET signal may be indicative of dissociation or association between BRET partners, but may also reflect conformational changes of the molecules, to which the donor or the acceptor is fused. In order to discriminate between these two possibilities, $BRET_{50}$ values are compared in cells incubated in the absence or presence of agonists. Conformational changes within BRET partners are revealed by identical $BRET_{50}$ and different $BRET_{max}$ values. In contrast, a significant variation of $BRET_{50}$ values, which reflects a change in the relative affinity of the partners, indicates ligand-induced association or dissociation of BRET partners.

Conformational changes within preformed receptor dimers have been documented for several receptors. EC_{50} values (the concentration of ligand, which

induces the half-maximal change of the BRET signal) have been determined for multiple ligands and for given ratios of BRET donor and acceptor pairs. Cumulated data obtained with the insulin receptor (a receptor with tyrosine kinase activity, Boute *et al*., 2001), the leptin receptor (belonging to the cytokine receptor family, Couturier and Jockers, 2003), and several GPCRs (Angers, *et al*., 2000; Ayoub *et al*., 2004; Percherancier *et al*., 2005) indicate that EC_{50} values are correlated with the affinity of the ligands (K_i). Owing to the unique feature of the BRET experiments, which is to focus the analysis on one given combination of receptors (those respectively fused to a BRET donor and a BRET acceptor), BRET can be used to determine the specific pharmacological profile of receptor heterodimers (Ayoub *et al*., 2004; Percherancier *et al*., 2005). Such information is difficult to obtain using classical radioligand competition binding assays, as ligands can potentially bind simultaneously to all available receptor species: monomers, homodimers, and heterodimers.

3.2. Monitoring protein translocation by BRET

BRET assays were successfully used to monitor regulated protein translocation in living cells. The first example of this approach is the recruitment of the GPCR-associated regulatory and signaling protein ß-arrestin to agonist-stimulated ß2-adrenergic receptors (Angers *et al*., 2000). Subsequent experiments with other GPCRs were reported to produce similar results. As expected, ß-arrestin recruitment to receptor was strictly agonist dependent and the observed EC_{50} values correlated with agonist affinities for corresponding receptors (Hanyaloglu *et al*., 2002; Terrillon *et al*., 2003). As the interaction with ß-arrestin is a general feature of most receptors of the GPCR superfamily, most of the orphan GPCRs (more than 100 remain to be characterized) should be capable of recruiting ß-arrestin in case of activation. Accordingly, a BRET-based screening assay for agonists of orphan GPCRs has been proposed (Bertrand *et al*., 2002) on the basis of receptor-ß-arrestin interaction.

During translocation to activated GPCR, ß-arrestins are ubiquitinated by the Mdm2 ubiquitin ligase (Shenoy *et al*., 2001). This phenomenon is believed to be critical for receptor endocytosis. The stability of ß-arrestin ubiquitination depends on the receptor that has initiated ß-arrestin translocation. Sustained ubiquitination of ß-arrestin, in turn, stabilizes the ß-arrestin-receptor association and affect the fate of internalized receptors (Shenoy and Lefkowitz, 2003). Receptors stably associated with ß-arrestins are principally sorted to lysosomes (degradative pathways), whereas receptors that interact weakly with ß-arrestin are mostly recycled to the plasma membrane. Recently, a BRET-based assay has been developed to study the dynamic of ß-arrestin ubiquitination (Perroy *et al*., 2004). The BRET donor (Rluc) was fused to the N-terminus of ß-arrestin and the BRET acceptor (GFP2) was fused to the N-terminus of Lys48Ala Lys63Ala ubiquitin, a ubiquitin mutant that cannot form polyubiquitin chains. The ubiquitination of Rluc-ß-arrestin by GFP2-ubiquitin results in a BRET signal, which is dynamically regulated by GPCR activation. On the basis of the stability of the BRET signal, the two classes of GPCR described above may be distinguished.

BRET assays have also been employed to monitor the interaction of an enzyme with its substrate, as shown for the tyrosine phosphatase PTP1B, which dephosphorylates tyrosine phosphorylated insulin receptors (Boute *et al*., 2003). Agonist stimulation of the insulin receptor induces receptor autophosphorylation on tyrosine residues and its subsequent internalization. The receptor is then dephosphorylated by PTP1-B. To stabilize the transient interaction between the receptor and the enzyme, a substrate-trapping mutant of PTP1B was used (D181A PTP1B). A BRET signal could be detected, upon insulin stimulation, in intact cells expressing an insulin receptor fused upstream of the luciferase, and the YFP-PTP1B D181A mutant.

In conclusion, there is no theoretical limit to the types of constitutive or regulated protein–protein interactions that can be studied by BRET, provided that the necessity of fusing BRET donors and acceptors to the proteins of interest does not perturb their biological properties. False-positive results, due to protein overexpression, can generally be avoided, because of the high sensitivity of the method, by simply scaling down the amount of transfected cDNAs until the amount of expressed fusion proteins becomes comparable to physiological concentrations. As discussed above, molecular interactions may not be detectable by BRET because the distance or the orientation of BRET donor and acceptor are not appropriate or when the interaction between the proteins of interest is too transient. In many cases, different positioning of BRET donors or acceptors or the creation of appropriate mutants can help overcome these limitations. We have no doubt that the BRET technology is just at its beginning and has a promising future.

Introductory Review

Probing cellular function with bioluminescence imaging

Guy A. Rutter, Gabriela da Silva Xavier, Takashi Tsuboi and Kathryn J. Mitchell

University of Bristol, Bristol, UK

John W. Hanrahan

McGill University, Montreal QC, Canada

1. Introduction

In this chapter, we describe luminescence-based methodologies that have been developed to monitor three key aspects of cellular biology in the context of single living mammalian cells or cell populations. Each of these methods is highly amenable to studying the function of proteins introduced into cells through: (1) co-overexpression of the wild-type protein with the reporters described, using a mammalian expression vector, adenoviral gene delivery (Andreolas *et al*., 2002), or transgenesis (Ma *et al*., 2004); (2) inactivation of the protein through RNA interference (da Silva Xavier *et al*., 2004; *see also* Article 60, **siRNA approaches in cell biology**, Volume 5); or (3) introduction of inactivating antibodies into single cells (da Silva Xavier, 2000b, 2004; Andreolas *et al*., 2002). As such, these are powerful techniques for the analysis of gene function.

2. Use of recombinant targeted luciferases for dynamic measurements of intracellular free ATP concentration

The maintenance of intracellular ATP, the cell's energy currency, is a fundamental concern for all living organisms. The use of firefly luciferase, targeted to discrete intracellular domains, provides an extremely sensitive method of monitoring free [ATP] dynamics at the subcellular level. Firefly (*Photinus pyralis*) luciferase uses ATP, luciferin, and oxygen as substrates to produce light with a quantum yield of 0.9:

$$\text{Luciferin} + \text{ATP} + \text{Mg}^{2+} + \text{O}_2 \rightarrow \text{oxyluciferin} + \text{AMP} + \text{PP}_i + \text{CO}_2 + \text{light} \quad (1)$$

Luciferase has previously been employed to measure intracellular ATP concentrations in single cardiac myocytes (Bowers *et al*., 1992) and hepatocytes (Koop and Cobbold, 1993), but only after microinjection of the purified protein. By expressing the recombinant protein from plasmids introduced by microinjection (Kennedy *et al*., 1999), transfection (Tsuboi *et al*., 2003), or the use of adenoviral vectors (Ainscow and Rutter, 2001), we have developed a single cell photon-counting method to image ATP concentrations dynamically and at the subcellular level in single cells (Kennedy *et al*., 1999). Importantly, the addition of targeting sequences to luciferase cDNA allows [ATP] to be imaged in a variety of subcellular domains, including the cytosol, mitochondria, and the subplasma membrane region (Kennedy *et al*., 1999). Given the feeble photon production of luciferase (a few photons per second per cell versus thousands of photons for fluorescent probes), imaging [ATP] at the single cell level requires highly sensitive cameras. There are, broadly speaking, two common types of photon-counting systems. The first involves the coupling of a charged multichannel plate coupled to a charge-coupled device (CCD). Here, a multichannel plate intensifier amplifies the signal up to 10^9-fold, thus giving a high signal-to-noise ratio. Various systems exist on the market (e.g., see websites for Photek, **www.photek.co.uk**, Hamamatsu-Photonics, **www.hamamatsu.com**, and Roper Scientific, **www.roperscientific.com**). Our imaging system consists of an Olympus IX-70 inverted microscope (×10 air objective, 0.4 numerical aperture) and a three-stage intensified CCD camera (Photek ICCD316; Photek, Lewes, E. Sussex, UK). We have used this system, in combination with recombinant targeted luciferases, to monitor changes in localized free [ATP] in a number of cell types (Ainscow *et al*., 2000; Ainscow and Rutter, 2001; Jouaville *et al*., 1999; Kennedy *et al*., 1999; Tsuboi *et al*., 2003) (Figure 1).

However, this type of system gives low spatial resolution. Back-thinned liquid crystal display (LCD) detectors have a lower signal-to-noise ratio as the signal is not amplified prior to detection. Signal-to-noise ratio can be improved through the use of better cooling systems, whereas cooled back-thinned integrating CCD cameras are preferred for imaging tissues (see below). However, at the time of writing, such systems only provide adequate sensitivity to detect changes in single cells over rather lengthy time frames (>10 s.data point^{-1}).

3. Using luciferase bioluminescence to measure release of intracellular ATP

Extracellular ATP is an important autocrine and paracrine signaling molecule. When released from damaged cells, it binds to purinergic (P2X) receptors on sensory neurons that signal pain. Thus, the activation of isolated nociceptors by cell extracts is abolished if the extracts are pretreated with apyrase to degrade ATP, or if P2X receptors on the neuron are blocked using the receptor antagonist, suramin (Cook and McCleskey, 2002). In addition to this pathological role, physiological ATP release mediates neurotransmission, vascular tone, cellular volume, responses to distension and infection, and many other physiological processes. There is thus great interest in measuring its extracellular concentration. Although systemic

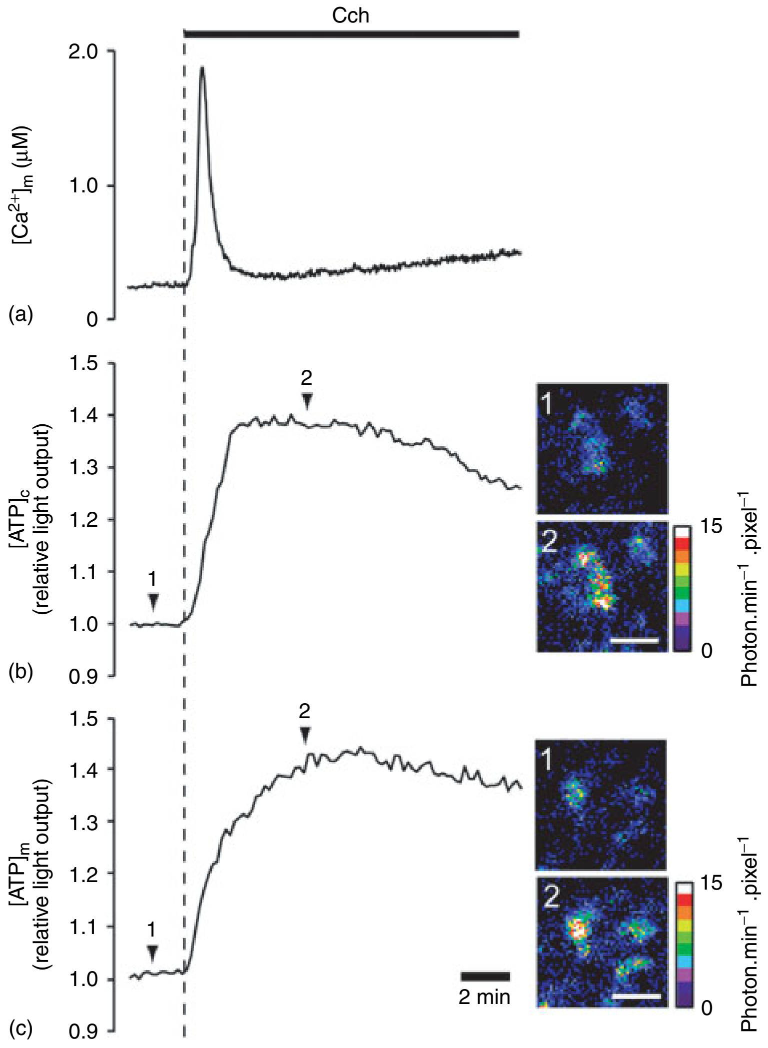

Figure 1 Effect of carbachol (Cch, 100 μM) on (a) mitochondrial $[Ca^{2+}]$, (b) cytosolic [ATP], and (c) mitochondrial [ATP] increases in pancreatic MIN6 β-cells. Typical traces from eight separate experiments are shown. The images in (b) and (c) show the monitored luminescence changes in a typical field of cells, imaged during 60 s, starting at the corresponding time points (1 and 2). The scale bar represents 50 μm

plasma [ATP] ranges are thought to range between 0.4 and 1.4 μM, interstitial ATP levels within tissues depend on local rates of release and degradation and can be much higher. For example, [ATP] is estimated to reach 68 μM at the surface of retinal astrocytes during mechanical stimulation (Newman, 2001), 25 μM at the surface of pancreatic beta cells (Hazama *et al*., 1998), and 14 μM beneath the macula densa during renal tubulo-glomerular feedback (Bell *et al*., 2003).

Luciferase bioluminescence has historically been the most widely used method for studying ATP release.

The most straightforward approach involves collecting samples of extracellular fluid and analyzing them in a luminometer. This approach is quantitative and readily yields an apparent ATP efflux rate. Problems with experimental interventions that could interfere with the luciferase reaction are also minimized. For example, gadolinium (Boudreault and Grygorczyk, 2002), which is often used to block stretch-activated cation channels, as well as suramin (Newman, 2001) are both luciferase inhibitors that can be removed before assay. However, collecting and analyzing ATP samples can be problematic as release by many cells is exquisitely mechano-sensitive. Simply tilting a culture dish gently during collection of samples from cultured airway epithelial cells can increase extracellular [ATP] by 10-fold (Grygorczyk and Hanrahan, 1997). This sensitivity is probably somewhat exaggerated in cultured cells since they are not subjected to constant mechanical stimulation as they would be in vivo. Nevertheless, mechanically induced ATP release is observed with freshly isolated tissues (e.g., Ferguson *et al*., 1997), and care must be taken to avoid physical manipulations and solution turbulence. An approach we have found useful involves culturing cells on porous capillaries in a hollow-fiber bioreactor, so that ATP release can be continuously collected in a flow-through system that provides control over shear stress (Guyot and Hanrahan, 2002).

An alternative to the sample-and-assay approach involves adding luciferase and luciferin to the bath and monitoring bioluminescence in situ. If all ATP were consumed by luciferase, release could be estimated simply by counting the photons generated. However, it is usually more practical to use conditions in which luminescence is proportional to the steady state [ATP] and to assume that a negligible fraction of released ATP is consumed by the luciferase reaction. A staircaselike signal is then obtained that could, in principle, be differentiated to give information about the rate of release (Taylor *et al*., 1998). One interesting method is that of Jans *et al*. (2002), who used a stopped-flow approach to determine ATP efflux rates.

A major advantage of extracellular luciferase for monitoring ATP release in situ comes from the spatial information it provides when combined with low light-level microscopy (e.g., Wang *et al*., 2000). Indeed, spontaneous bursts of ATP release are observed in some conditions (Arcuino *et al*., 2002), which may be mediated by connexin hemichannels (Cotrina *et al*., 1998). On the other hand, vesicular ATP release was observed when intracellular calcium was elevated in astrocytes by the glutamergic agonist AMPA (α-amino-3-methyl-4-isoxazolepropionic acid) and during stimulation by the protein kinase C activator PMA (phorbol 12-myristate 13-acetate) (Coco *et al*., 2003).

ATP at the cell surface is most relevant for extracellular signaling since it bathes the purinoceptors. A novel application of the extracellular luciferin-luciferase reaction has been used to monitor ATP release by isolated pancreatic acini (Sørensen and Novak, 2001). Rather than measuring the bioluminescence signal, the decrease in fluorescence between 510 and 550 nm caused by oxidation of luciferin was used to monitor luciferase activity and, thus, [ATP].

4. Imaging free intracellular Ca^{2+} concentration

Changes in intracellular free Ca^{2+} concentration play a crucial role in the control of cellular function (Rutter, 1998a; Berridge *et al*., 2003). Since its identification and characterization (Shimomura *et al*., 1962), the Ca^{2+}-sensitive bioluminescent protein aequorin, from the jellyfish *Aequorea victoria*, has provided an invaluable tool for the dynamic measurement of intracellular Ca^{2+} ion concentration. Aequorin exists in its native form in a complex with its coenzyme, coelenterazine, and reports changes in Ca^{2+} concentration via an oxidation reaction that produces blue light (Head *et al*., 2000). Microinjection of purified aequorin has been extensively used to monitor Ca^{2+} signaling in a wide spectrum of cell types, including bacteria, arthropods, plants, and mammalian cells. A key technological advance occurred following the cloning of aequorin (Inouye *et al*., 1985), which allowed the generation of recombinant aequorin constructs. Furthermore, the generation of aequorin mutants with decreased Ca^{2+} sensitivity (Kendall, *et al*., 1992) and the ready availability of synthetic coelenterazine analogs have resulted in the generation of several organelle-targeted aequorins able to monitor lumenal Ca^{2+} concentration changes with high specificity. Applied for the first time to monitor free Ca^{2+} concentration in the mitochondria of endothelial (Rizzuto *et al*., 1992) and pancreatic β- (Rutter *et al*., 1993) cells, recombinant aequorin was subsequently used to measure Ca^{2+} concentrations in the sarco- and endoplasmic reticulum (Montero *et al*., 1995), nucleus (Brini *et al*., 1993), Golgi apparatus (Pinton *et al*., 1998), dense core secretory vesicle surface (Pouli *et al*., 1998) and interior (Mitchell, *et al*., 2001), as well as the bacterial periplasm (Jones *et al*., 2002).

The use of aequorin does have disadvantages compared to the use of fluorescent Ca^{2+} probes (Miyawaki *et al*., 1997). Thus, the very limited amount of emitted light enforces severe limitations on single cell or suborganellar imaging (Rutter *et al*., 1996). Moreover, when measuring [Ca^{2+}] in compartments with relatively high steady state levels ($>10\,\mu M$), reconstitution of aequorin with coenzyme requires previous complete depletion of Ca^{2+}, a procedure that may have deleterious effects on the cell. Irreversible destruction of the aequorin complex, combined with the high rate of consumption at steady state, also restrict experiment duration. On the positive side, aequorin can be used to measure Ca^{2+} concentration over a wide range (100 nM to $>500\,\mu M$), and calibration of the emitted light output is made easy by the use of a simple algorithm (Rutter *et al*., 1993). The major advantage of using aequorin, however, is that it is much less severely inhibited at low pH values (<6.0) (Blinks, 1989; Rizzuto *et al*., 1994) than green fluorescent protein (GFP)-based Ca^{2+}-sensitive indicators, for example, cameleons (Miyawaki *et al*., 1997; Llopis *et al*., 1998; Baird *et al*., 1999; Emmanouilidou *et al*., 1999), which detect changes in local Ca^{2+} concentrations using fluorescence resonance energy transfer (FRET) between a cyan-emitting mutant of GFP and an enhanced yellow-emitting GFP, linked by the calmodulin-binding peptide M13. This fundamental property of aequorin becomes crucial when measuring Ca^{2+} concentrations within acidic organelles, such as dense core secretory vesicles whose pH are approximately 5.5

(Urbe *et al*., 1997). Indeed, using a chimaeric-aequorin targeted to the secretory vesicle matrix (Mitchell *et al*., 2001), dense core vesicles have recently been revealed as an important intracellular Ca^{2+}-store involved in ryanodine receptor and nicotinic acid adenine dinucleotide phosphate (NAADP)-mediated intracellular Ca^{2+} signaling and the regulation of insulin secretion (Mitchell *et al*., 2003).

5. Measuring gene expression in single cells and whole organisms using luminescent probes

Bioluminescent reporter genes have also proven to be invaluable in the study of regulated gene expression. Common genetic reporters include bacterial luciferases (bacterial *lux* gene products), firefly (*Photinus*) luciferase, β-galactosidase, β-glucuronidase, alkaline phosphatase, green fluorescent protein, β-lactamase, and human growth hormone (Rutter *et al*., 1998b).

The use of firefly luciferase as a reporter has increased in popularity because of the development of a “constant light” luciferase assay, which allows rapid, quantitative dynamic imaging of gene expression. Commonly, firefly luciferase is coupled with the use of β-galactosidase or β-glucuronidase to allow the expression of the regulated gene to be normalized to that of one which is constitutively expressed. Since changes in free ATP concentration can potentially interfere with measurements with luciferase (see above), it is usually necessary to assess if the experiment results in a net change in ATP content; usually, these changes are small ($<15\%$) and can frequently be neglected in the face of manyfold changes in the activity of a promoter.

Our own dual reporter system involves the promoter of interest fused upstream of the firefly luciferase gene and the cytomegalovirus promoter fused upstream of the *Rotylenchulus reniformis* gene. The reporter gene-bearing plasmids are introduced into cells by transient or stable transfection, or via microinjection. The signal output from firefly and *R. reniformis* luciferases are assessed using a sensitive photon-counting camera (see above) upon addition of luciferin and coelenterazine, respectively (Kennedy *et al*., 1997; da Silva Xavier, *et al*., 2000a; da Silva Xavier *et al*., 2000b; Rafiq *et al*., 1998; Campbell *et al*., 1999; Wu *et al*., 1999; Rafiq *et al*., 2000; Palmer *et al*., 2002; Andreolas *et al*., 2002; Stirland *et al*., 2003).

The use of bioluminescent reporters offers some key advantages over that of fluorescent reporters based on GFP (Chalfie *et al*., 1994; Heim and Tsien, 1996). In the case of GFP, the lack of linearity between protein concentration and fluorescence intensity, as well as interference from cellular autofluorescence (Rutter *et al*., 1998b) significantly limits sensitivity. Moreover, the maturation time of GFP is typically between 2 and 4 h (Siemering *et al*., 1996) such that it cannot easily be used for the monitoring of oscillatory changes in gene expression. This problem is even more acute for the use of β-lactamase and probes based on FRET (Zlokarnik *et al*., 1998), where the accumulation of a cleaved product is involved. At present, measurements of such dynamic changes can only readily be achieved at the single cell level using luciferase, as demonstrated in both mammalian cells (Stirland *et al*., 2003) and plants (Millar *et al*., 1995).

Luciferase-based technologies can also be applied to whole organisms. Imaging in whole plants (Riggs and Chrispeels, 1987) and in rodents (DiLella *et al*., 1988) was first described in the late 1980s. The technology available for the transfer into and imaging of reporter genes in whole organisms has improved considerably in recent years (Contag and Bachman, 2002; Greer and Szalay, 2002). For this application, cooled CCDs are more suitable than image-intensified CCDs, as the former have higher quantum efficiency (approximately 85%) (Rice *et al*., 2001). Luminescent reporters can now be introduced into whole organisms through the use of replication-deficient adenoviruses, while transgenic organisms expressing reporter genes have also been produced to study specific processes within the whole organism. A recent elegant study by Yamaguchi *et al*. (2001) showed that real time in vivo gene expression could be performed over a prolonged period of time to monitor the oscillatory expression of luciferase in living mouse brain.

6. Conclusions

Bioluminescent proteins are now able to provide a means to measure multiple aspects of cellular behavior. The engineering of probes already known, and the discovery of new variants, should allow us to measure an even larger range of cell functions in the future.

Small molecule fluorescent probes for protein labeling and their application to cell-based imaging (including FlAsH etc.)

Tony Cass

Institute of Biomedical Engineering, Imperial College London, London, UK

1. Site-specific labeling with bis(arsenicals)

The familiar fluorescent labeling chemistries that have been extensively employed over many years are nowhere near sufficiently specific to be used to label a single protein in the complex milieu of a cell. The broad reactivity of groups such as *N*-hydroxysuccinimide (amines) or iodoacetamide (thiol) precludes their use in specific labeling of a singular cellular component. To achieve this, both a specific labeling reagent and a specific target sequence are necessary. The latter can be readily fused to any given protein so allowing a targeted labeling by the former. In addition to its specificity, the labeling reagent should be cell permeant and ideally nonfluorescent until it has reacted with the target sequence. Griffin *et al*. (1998) described a fluorescein-derived bis(arsenical) that reacted with a tetracysteine motif (CCXXCC) in a proposed α-helix. The chelate effect gives this compound a high (<nM) affinity for the cognate peptide so avoiding the labeling of other cellular cysteine-containing proteins and the potential toxicity arising from there. To further reduce toxicity, FlAsH is added as an ethanedithiol conjugate (FlAsH-EDT_2, Figure 1a) that undergoes dithiol exchange with the target peptides. In a subsequent publication (Adams *et al*., 2002), a more detailed analysis of the reaction of FlAsH and a resofufin analog (ReAsH, Figure 1b) with tetracysteine peptides is described. The apparent K_d values are in the pM range for optimum peptide sequence, where the latter was found to contain CCPGCC. The presence of the proline glycine sequence suggests that a hairpin rather than α-helix is the preferred conformation.

Nakanishi and coworkers in two papers (Nakanishi *et al*., 2001; Nakanishi *et al*., 2004) described similar bis(arsensical) derivatives of Nile Red (BArNile-EDT_2, Figure 1c) that could be used to label tetracysteine sequences fused to proteins in live cells. The fluorescence of Nile Red is sensitive to the hydrophobicity of its local environment and this was exploited to measure calcium-dependent conformational

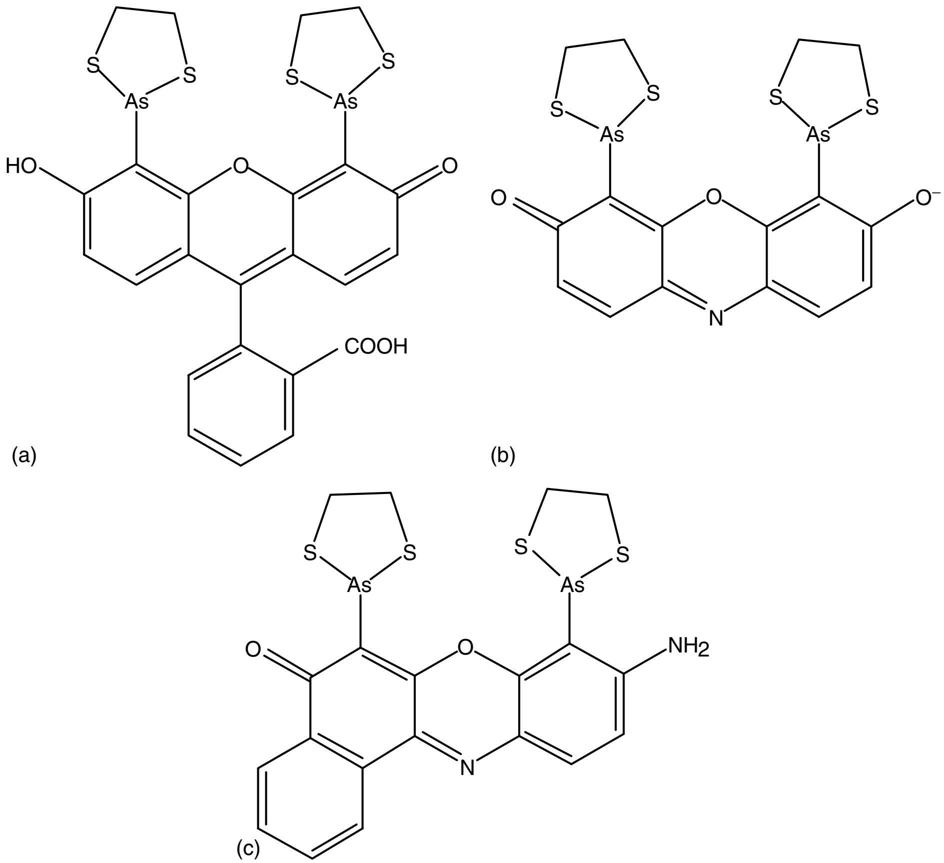

Figure 1 Structures of the bis(arsenical) fluorescent dyes that have been used to label tetracysteine peptide sequences in proteins expressed in live cells. (a) FlAsH-EDT$_2$. (b) ReAsH-EDT$_2$. (c) BArNile-EDT$_2$

changes in a calmodulin derivative. In their second paper (Nakanishi *et al*., 2004), this group further improved on the calcium responsiveness of their conjugates by incorporating a benzoic acid group.

One potential difficulty associated with in vivo labeling is the nonspecific attachment to other proteins, either due to cross-reaction with other cysteine-containing sequences or the natural occurrence of the target sequence. Both Griffin *et al*. (2000) and Stroffekova *et al*. (2001) identified nonspecific binding of FlAsH although they attributed it to different reasons (binding of the fluorophore to hydrophobic sites and reaction with other cysteine-containing proteins respectively).

2. Applications of in vivo labeling with bis(arsenicals)

In their original paper, Griffin *et al*. (1998) demonstrated the in vivo labeling of a tetracysteine-tagged enhanced cyan fluorescent protein (ECFP) via fluorescence resonance energy transfer (FRET) from the FlAsH moiety to the protein

fluorophore. Subsequent applications of this in vivo labeling method have been described and include the attachment of both FlAsH and ReAsH to tagged connexin43 (Gaietta *et al*., 2002; Sosinsky *et al*., 2003) to following trafficking of this protein across gap junctions. The availability of two different fluorophores that labeled cells at different time intervals allows the distinction between "old" and "young" protein and tracing of their individual fates (Gaietta *et al*., 2002). Moreover, the ReAsH moiety was able to bring about photopolymerization of 3,5-diaminobenzene so generating osmiophilic stains for subsequent electron microscopy so allowing localization of the labeled proteins at higher resolution than can be achieved by fluorescence microscopy. Many of the proteins that have been labeled in vivo have been recombinantly expressed in the host cell, however, this is not the only method by which a tetracysteine (TetCys) tag can be introduced; Andresen *et al*. (2004) used integrative epitope tagging to attach a TetCys tag (GSSGCCPGCC) to open reading frames (ORFs) in the chromosomes of the budding yeast *Saccharomyces cerevisiae*. To demonstrate this approach, these authors tagged β-tubulin and FlAsH-labeled it. In a systematic study of multiple TetCys tags as well as GFP (Green Fluorescent Protein), they demonstrated that the smaller tags (10-amino acids) had a less deleterious effect than the larger ones (20- or 30-amino acids) or than GFP on cell viability. After labeling, the modified tubulin was integrated into microtubules and could be readily imaged. In contrast to both Griffin *et al*. (2000) and Stroffekova *et al*. (2001), Andresen *et al*. (2004) observed very little nonspecific labeling in yeast cells.

In addition to its use for imaging, FlAsH-modified proteins have also been employed to selectively destroy the proteins to which they are attached by illumination of the cells at 488 nm. Marek and Davis (2002) demonstrated selective inactivation of FlAsH-modified synaptotagmin.

3. Alternative tag-selective labeling approaches

Several other examples of tag selective in vivo labeling chemistries have been described in the past 4 years, and while they differ in detail, they have the common aim of providing as unique as possible a site at which to attach the fluorophore (or other conjugating molecule).

Native chemical ligation exploits the unique reactivity of the thiol group of an N-terminal cysteine residue with thioesters and has been widely utilized in vitro for the attachment of many different small molecules site specifically to the N-terminus of target proteins (Yeo *et al*., 2004), as shown in Figure 2. While this technology has many uses, in the context of this review, it is the observation that the reaction shown in Figure 2 also occurs in vivo. The rarity of proteins with a natural N-terminal cysteine means that heterologous expression of a recombinant protein with an engineered N-terminal cysteine is selectively modified. Yeo *et al*. (2003) exploited exactly this approach to label glutathione-*S*-transferase (GST) having an engineered N-terminal cysteine with a variety of fluorophores in live *Escherichia coli* cells.

Strong, noncovalent interactions of suitable specificity can also form the basis of in vivo labeling methods. Miller *et al*. (2004) have taken advantage of the high

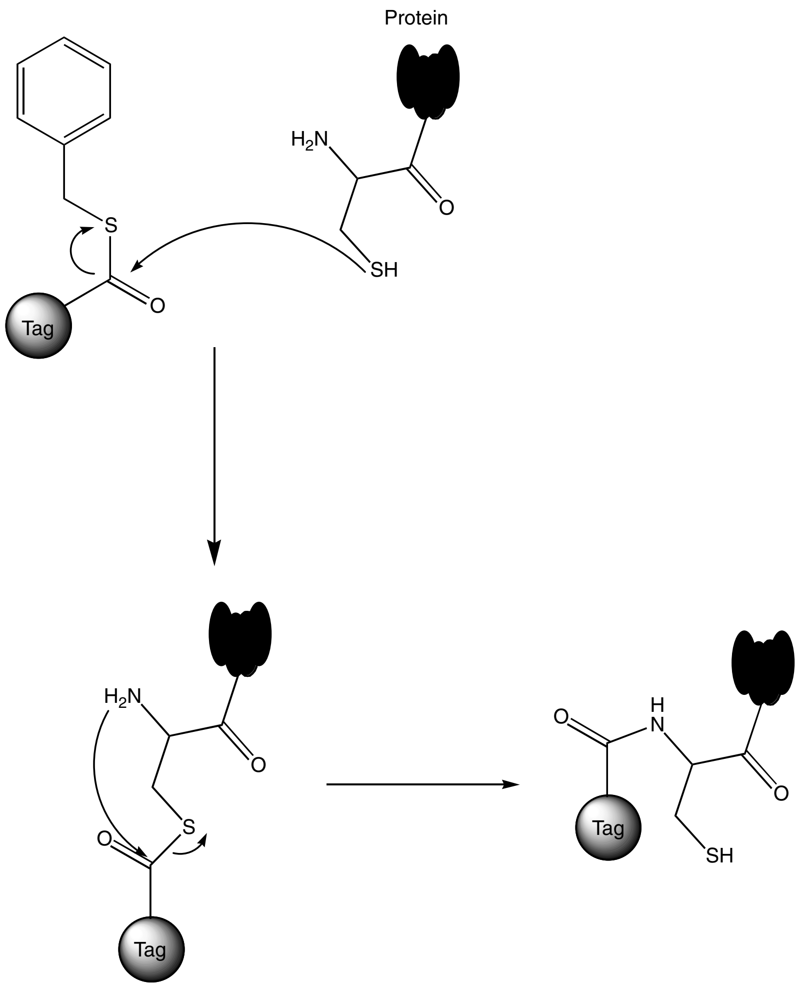

Figure 2 Native chemical ligation for the introduction of tags to proteins carrying an N-terminal cysteine residue

affinity (<nM) and slow dissociation rates (10^{-4} s^{-1}) of methotrexate derivatives from dihydrofolate reductase (DHFR) to target a fluorescent methotrexate to a DHFR fusion protein. To avoid binding to endogenous DHFR, the experiments were performed in $DHFR^{-}$ CHO (Chinese Hamster Ovary) cells. Fusing a myristoylation/palmitoylation sequence targeted the protein to the plasma membrane where the fluorescent dye was subsequently concentrated. To overcome the endogenous DHFR background, the authors propose to engineer DHFR to bind methotrexate derivatives not bound by the native protein. This particular method has close similarities to the well-established use of GFP fusion proteins. The smaller size of DHFR and the wider range of synthetic fluorophores may offer some advantages; however, overcoming the endogenous DHFR background will be essential to its further use.

An alternative approach is based on the specific covalent modification of fusion proteins that exploits the transfer of functional groups from alkylated guanine bases to the DNA repair enzyme O^6-alkylguanine-DNA alkyltransferase (hAGT). The reaction of hAGT with a labeled O^6 guanine derivative is shown in Figure 3. Methods to synthesize the labeled O^6 guanine derivatives were developed by Kindermann *et al*. (2004), and a mutant hAGT enzyme (W160) evolved to show a higher activity against O^6 benzylguanosine (Juillerat *et al*., 2003). Keppler *et al*., (2003, 2004a) demonstrated the transfer of a label to hAGT fused to CFP (cyan fluorescent protein), DHFR, GST, and a trimeric nuclear localization sequence from the SV40 large T antigen. Labeling of these fusion proteins was demonstrated in *E. coli*, *S. cerevisiae*, and CHO cells. Further, exemplification of this approach

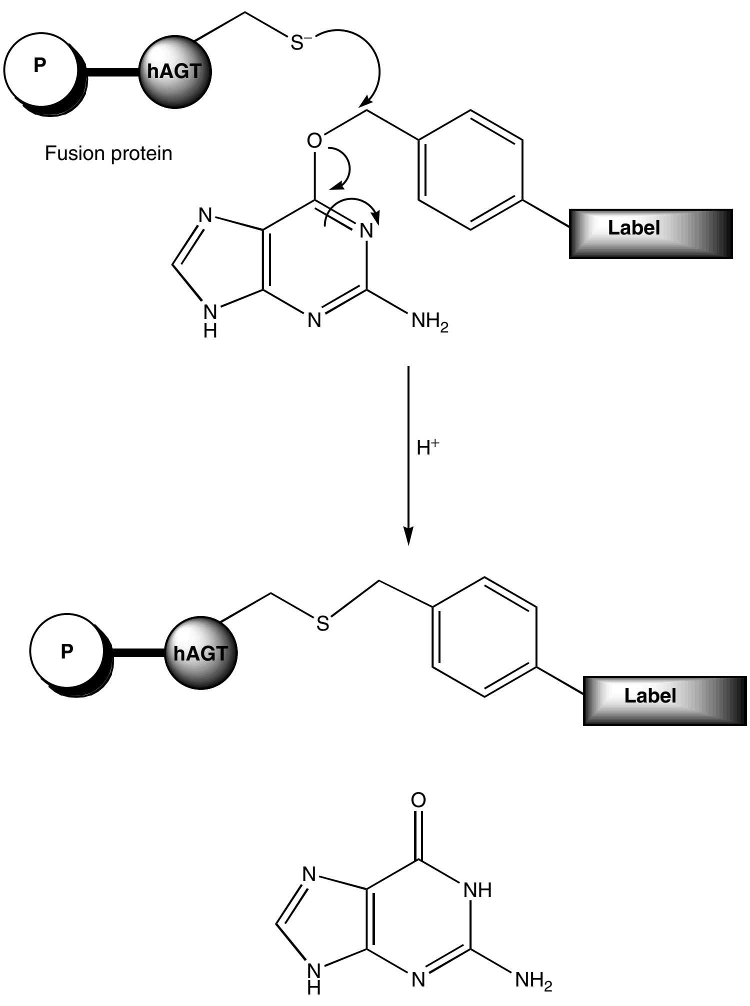

Figure 3 The mechanism of labeling of O^6-alkylguanine-DNA alkyltransferase fusion proteins with benzyl guanine derivatives

with a variety of animal cells was described by Keppler *et al*. (2004b), who fused different cell localization sequences to the hAGT and then labeled the expressed proteins in living cells.

4. Specific labeling of membrane proteins

Recently, Vogel and coworkers have described two approaches to live cell labeling of specific membrane proteins. Guignet *et al*. (2004) exploited the well-known ability of hexahisitdine tags to bind to nickel nitrilotriacetate (NTA) complexes. A nickel NTA complex modified with a fluorescent reporter group was found to complex with hexahisitdine-tagged membrane proteins (ionotropic and G-protein coupled receptors). The affinity of the metal chelate complexes were modest (μM), however, this was sufficient for imaging the proteins in cells.

Site-specific labeling of cell surface proteins has also been demonstrated by George *et al*. (2004) using an enzyme reaction (phosphopantetheine transferase (PPTase)). This enzyme transfers a modified CoA to a serine residue of the acyl carrier protein (ACP) fused to the membrane protein of interest. The fluorescent dye Cy3 labeled CoA was shown to be transferred to ACP fused to two membrane proteins (α-agglutinin receptor and neurokinin-1).

5. Conclusions

The past few years have seen a plethora of new approaches to the specific labeling of proteins in live cells. A combination of mutagenesis, heterologous expression, and fluorophore synthesis has generated new reagents for imaging the localization and trafficking of specific proteins that complement the now well-established GFP fusions.

Two directions for the development of this technology are signposted by recent work: the introduction of even less perturbing modifications and the use of these methods not just to follow protein localization but to use the proteins as indicators of ligand concentrations for both large and small molecules.

Specialist Review

Using photoactivatable GFPs to study protein dynamics and function

Dmitry M. Chudakov and Konstantin A. Lukyanov
Institute of Bioorganic Chemistry, Moscow, Russia

1. Introduction

Green fluorescent protein (GFP) from hydroid jellyfish *Aequorea victoria* (Johnson *et al*., 1962; Prasher *et al*., 1992) and its mutants have transformed cell and molecular biology. Over the past few years, a number of GFP homologs of different colors including cyan, green, yellow, red fluorescent proteins, and nonfluorescent purple-blue chromoproteins have been identified and extensively characterized (Matz *et al*., 1999; Lukyanov *et al*., 2000). GFP-like proteins have been found not only in Cnidaria (in corals Anthozoa and jellyfishes Hydrozoa) but also in copepods (Arthropoda, Crustacea) (Shagin *et al*., 2004). The most remarkable feature of GFP-like proteins is their ability to form an intrinsic chromophore within the protein globule without the assistance of any other proteins or cofactors except oxygen (Heim *et al*., 1994). What makes the GFP family of proteins prominent is the fact that they represent the only genetically encoded fluorescent tags that can be widely used to label organisms, cells, organelles, and proteins, as well as to develop molecular sensors for different aspects of intracellular environment (Lippincott-Schwartz and Patterson, 2003; Verkhusha and Lukyanov, 2004).

GFP has turned out to be a very suitable tag for photobleaching experiments. It produces bright, stable fluorescence that does not fade at low levels of illumination. By contrast, with high illumination levels, the GFP fluorophore can be photobleached. Under conditions where the light intensity used for photobleaching does not noticeably perturb living cells (Patterson *et al*., 1997), a variety of photobleaching methods can be employed to monitor protein and organelle dynamics. This includes FRAP (fluorescence recovery after photobleaching) or FLIP (fluorescence loss in photobleaching), which can give information about protein diffusion rate, mobile fraction, and exchange rate between bleached and unbleached areas (Lippincott-Schwartz *et al*., 2003; *see also* Article 53, **Photobleaching (FRAP/FLIP) and dynamic imaging**, Volume 5). However, these techniques do not enable direct tracking of the chosen object's movement using its fluorescent signal as the bleached proteins are invisible.

In order to directly monitor the trafficking of a specific population of tagged proteins, other methods had to be developed. One method used photobleaching of an acceptor protein in a FRET (fluorescence resonance energy transfer) pair, which resulted in an increase in donor protein fluorescence (Marchant *et al*., 2001). An alternative FLAP (fluorescence localization after photobleaching) technique was also reported (Dunn *et al*., 2002), involving two fluorophores, one of which is bleached and the other is used as a fluorescent control. The FLAP signal was calculated as the difference between the intensity of the light emitted by the two fluorophores. For reliable direct tracking, however, it has been necessary to develop directly photoactivatable fluorescent proteins, that is, proteins in which light of definite wavelength and intensity induces structural changes leading to the appearance of novel and greatly enhanced fluorescent signal. Several important advances have recently been reported in the development of such photoactivatable fluorescent proteins, and these are discussed below.

2. GFP photoactivation

The GFP fluorescence excitation spectrum has two peaks - with maxima at 396 nm and 476 nm, which correspond to two close emission peaks with maxima at about 505 nm. Two excitation peaks, with a 6:1 ratio, correspond to protonated (neutral) and deprotonated (anionic) chromophore forms (Chattoraj *et al*., 1996; Niwa *et al*., 1996; Brejc *et al*., 1997). In 1996, it was reported that UV irradiation causes reproportioning of excitation peaks in favor of the 476-nm peak (Yokoe and Meyer, 1996). That was the first time that GFP had been shown to be capable of photoactivation. However, the contrast between the photoactivated and initial 476-nm-excited GFP fluorescence reached only threefold. This contrast was insufficient for most experiments, and the technique was not widely adopted.

A mechanism for UV-induced GFP photoconversion has been revealed more recently (van Thor *et al*., 2002) (Figure 1a, right panel). Mass-spectral and crystallographic studies of the photoconverted protein showed that decarboxylation of Glu222 occurs during this process. As a result, a proton transfer pathway responsible for the equilibrium between the protonated and deprotonated states of chromophore becomes disrupted. Thus, the chromophore in photoconverted GFP exists mainly in the anionic state, absorbing light at about 480 nm.

In 2002, a GFP mutant was reported (Patterson and Lippincott-Schwartz, 2002), capable of much more effective photoactivation. This mutant protein, named PA-GFP, contains a single T203H substitution that resulted in the prevalence of protonated chromophore state before photoactivation. In this state, the protein is characterized by a single absorption/excitation peak at 400 nm and green fluorescence at 517 nm (Figure 1a, Table 1). Thus, PA-GFP gives almost zero fluorescence when excited at 480–500 nm. Intense UV-violet light irradiation (about 400 nm) causes irreversible chromophore photoconversion to the anionic form, which possesses absorption/excitation maximum at 504 nm. The contrast in the 504 nm-excited fluorescence before and after PA-GFP activation reaches 100-fold, making it suitable for many applications.

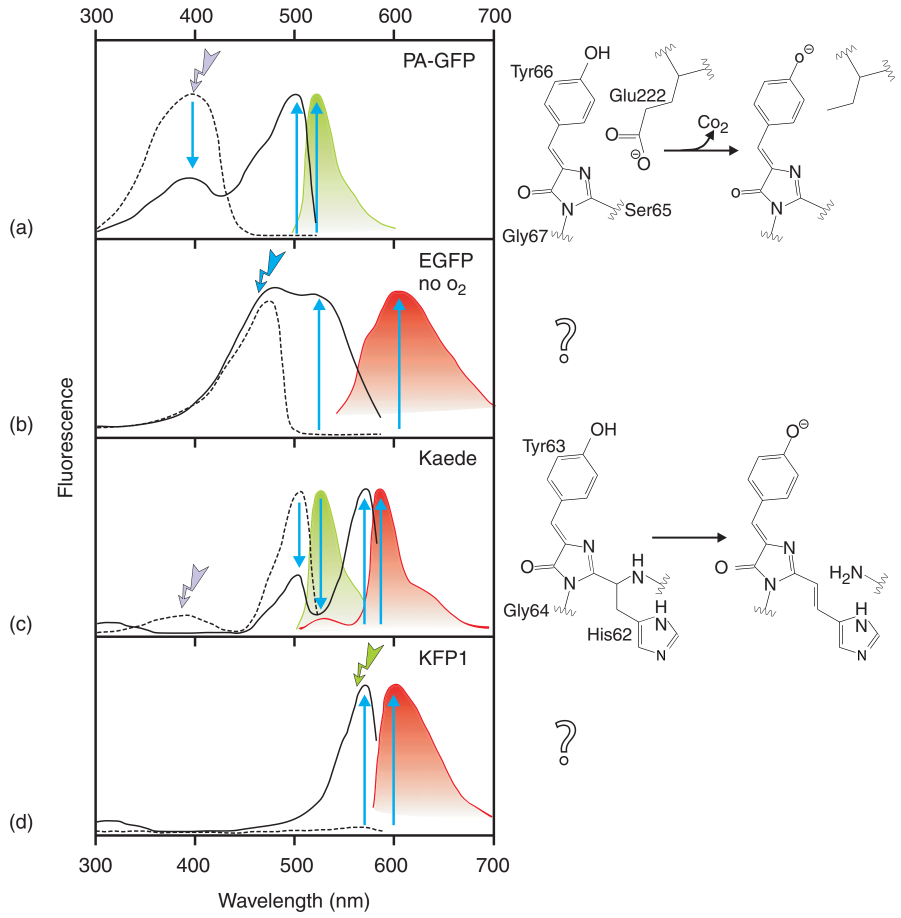

Figure 1 Schematic representation of spectral and structural changes underlying photoactivatable proteins conversion. Left: Excitation spectra before (dashed lines) and after (solid lines) photoactivation are shown black. Colored filled graphs show emission spectra. Straight blue arrows show spectral changes during photoconversion. Zigzag arrows show activating light. Right: Molecular mechanisms underlying photoactivation are shown for PA-GFP and Kaede

3. GFP photoactivation in anaerobic conditions

Evolution of this theme resembles a detective story. Soon after GFP photoactivation in aerobic conditions was published (Yokoe and Meyer, 1996), it was discovered that blue light (488 nm) GFP irradiation under anaerobic conditions made it red fluorescent (Elowitz *et al*., 1997; Sawin and Nurse, 1997). In the activated state, GFP possessed broad excitation-emission peaks at 525 and 600 nm, respectively (Figure 1b). This technology allowed red fluorescent signal activation and in vivo tracking of the movement of cellular proteins. The monomeric properties of GFP made it a useful tool, though restricted its application to anaerobic systems. This method was successfully applied (Elowitz *et al*., 1999) to measure a GFP diffusion coefficient in *Escherichia coli*.

Table 1 Photoactivatable fluorescent proteins

		PA-GFP	Kaede	KFP1[a]
Oligomeric state		Monomer	Tetramer	Tetramer
Activating light		UV-violet	UV-violet	Green
Quenching light		-	-	Blue, max at 450 nm
Excitation changes, nm		400–504	508–572	Growth at 590
Emission changes, nm		-	518–580	Growth at 600
Photoactivation reversibility		Irreversible	Irreversible	Reversible or irreversible
Fluorescence increase, fold		100	800	70 or 35
Ratio change, fold		~200	2000	-
Before activation	QY[b]	0.13	0.88	<0.001
	EC[c]	20 700	98 800	123 000
	pK_a	4.5	5.6	n.d.
	Brightness[d]	0.08	2.64	<0.004
After activation[a]	QY[b]	0.79	0.33	0.07
	EC[c]	17 400	60 400	59 000
	pK_a	n.d.	5.6	n.d.
	Brightness[d]	0.42	0.60	0.13

Protein advantages as a photoactivatable label are marked green, drawbacks - red.
[a]Contrast, quantum yield, and extinction coefficient after activation are given for the irreversibly kindled KFP1.
[b]QY, quantum yield.
[c]EC, extinction coefficient, $M^{-1}\,cm^{-1}$.
[d]As compared to brightness (extinction coefficient multiplied by quantum yield) of EGFP.

Sacchetti *et al*. (1999) reported that photoactivatable red signal observed in bacteria is produced by endogenous porphyrins, but not by the photoactivated GFP. Indeed, a substance they purified from *E. coli* definitely looked like porphyrins, according to the data given. Nevertheless, a marked difference in the shape of emission spectra between porphyrins and red photoactivated GFP gave rise to doubts.

In 2003, a novel article was published (Jakobs *et al*., 2003), describing a new successful application of GFP photoconversion to red form for investigating the continuity of mitochondrial matrix in living yeast. The authors also showed that fluorescence lifetime for the red photoconverted GFP chromophore is 2.11 ns, which was close to the usual green GFP fluorescence lifetime but not to that of porphyrins (about 15 ns).

Summing up, GFP photoconversion to the red fluorescent form under anaerobic conditions is a real phenomenon, which could be applied to object tracking within oxygen-free systems. Unfortunately, as GFP chromophore maturation necessarily requires oxygen, this technique was restricted to facultative anaerobes.

In contrast to GFP photoactivation under aerobic conditions, where the events underlying the photoconversion are generally clear (van Thor *et al*., 2002), the mechanism of GFP photoconversion to red fluorescent form remains unclear. This mechanism probably hides new important information about GFP chromophore functioning and also clues to the development of novel photoactivatable proteins.

4. Kaede

An intriguing fluorescent protein was cloned in 2002 from a stony coral *Trachyphyllia geoffroyi* (Ando *et al*., 2002). This protein was named "Kaede" ("Kaede" means a maple leaf in Japanese). In the dark, Kaede matures to a green fluorescent form. In response to UV-violet light irradiation, Kaede undergoes irreversible photoconversion to a red fluorescent form (Figure 1c, Table 1).

Soon after the Kaede discovery, the structural basis for its photoconversion was revealed (Mizuno *et al*., 2001) (Figure 1c, right panel). First, a usual GFP-like green-emitting chromophore is formed by His62-Tyr63-Gly64. Then, a red-emitting chromophore is formed under UV light irradiation as a result of protein backbone cleavage between amide N and αC of His62 and subsequent double bond formation between αC and βC of His62. Thus, the Kaede red chromophore includes the His62 ring in its conjugated π-system. The resulting increase in the red-to-green fluorescence ratio after photoactivation reaches more than 2000-fold, making it the most contrasting photoactivatable fluorescent protein currently developed.

5. Kindling fluorescent proteins (KFPs)

This group of photoactivatable proteins arose from a unique natural protein, which determines purple coloration of tentacles of sea anemone *Anemonia sulcata*. This protein was designated as asFP595 (Lukyanov *et al*., 2000), although it is variously also referred to asCP562 (Wiedenmann *et al*., 2000), asCP (Gurskaya *et al*., 2001), and asulCP (Labas *et al*., 2002). We will use the last designation.

Initially nonfluorescent asulCP becomes red fluorescent in response to irradiation with intense green light (kindling) and then relaxes back to a nonfluorescent state (Lukyanov *et al*., 2000). Blue light (action spectrum peaked at 450 nm) instantly reverts the activated protein to the nonfluorescent state (quenching). For the wild-type protein, both kindling and quenching are completely reversible processes.

Several mutants of asulCP with altered characteristics of kindling and quenching were generated (Chudakov *et al*., 2003a,b). Moreover, similar photoactivation behavior was transferred to two nonkindling, nonfluorescent coral chromoproteins, hcriCP from *Heteractis crispa* and cgigCP from *Condilactis gigantea* (Gurskaya *et al*., 2001), by point mutations of the chromophore environment (Chudakov *et al*., 2003a). All KFPs become red fluorescent after kindling (excitation peak at 580–590 nm, emission peak at 600–630 nm). Importantly, most mutants were capable of irreversible kindling in response to the more intense and/or enduring irradiation. The best mutant kindling variant of asulCP, named KFP1 (Chudakov *et al*., 2003b), demonstrated about a 70-fold reversible or 35-fold irreversible fluorescence increase in response to irradiation by intense green-yellow light (Figure 1d, Table 1).

Most probably, reversible photoactivation of KFPs can be explained by changes in protein conformation (chromophore cis-trans isomerization and/or rearrangement of chromophore and environment). However, the exact nature of both reversible and irreversible kindling effects remains unclear, waiting for further investigations.

6. Practical use of PA-GFP, Kaede, and KFP1

Among the GFP-like photoactivatable tags, only three proteins, PA-GFP, Kaede, and KFP1 are currently suitable for a wide range of practical applications (green-to-red GFP conversion requires anaerobic conditions and thus cannot be used in most biological models). Three "levels" of photolabeling could be recognized: labeling of whole cells, cell organelles, and proteins. Examples of potential applications of precise photolabeling are summarized in Table 2. In fact, photoactivatable proteins can find their use in any task aimed at monitoring the dynamics of objects in complex environments.

The photoactivation process could be divided onto three main steps: primary visualization of a photoactivatable tag, its precise photoactivation in a selected area, and tracing the resulting fluorescent signal. These steps differ significantly for PA-GFP, Kaede, and KFP1. Before activation, the green fluorescence of PA-GFP is visible under UV-violet light excitation (low-intensity light must be applied to PA-GFP to avoid premature photoconversion). Kaede initially represents a conventional GFP, thus it can be viewed when excited with blue light. Visualization of nonfluorescent KFP1 is possible due to reversible kindling by green light of medium intensity.

Irreversible photoactivation of a target object is achieved by strong irradiation with UV-violet (for PA-GFP and Kaede) or green (for KFP1) light. After photoconversion, PA-GFP acquires a new excitation peak at 504 nm. Its green fluorescence can be viewed in blue light against nonfluorescent background of nonactivated protein. Activated Kaede becomes red fluorescent and can be discriminated easily from green nonactivated protein. Irreversibly kindled KFP1 fluoresces red. It can be visualized after excitation with weak green light insufficient

Table 2 Potential applications of photoactivatable fluorescent proteins

Precise optical labeling of . . .	Possible areas of investigation
Cells	Cell tracking in individual development.
	Lymphocyte tracking.
	Cell tracking in cancer and metastasis.
	Tracking of free-living and pathogenic unicellular organisms.
Organelles	Visualization of individual cells of intricate shapes (e.g., neurons) in a complex network.
	Rate and direction of intracellular movement of organelles.
	Investigation of organelle continuity.
	Interchange of contents between organelles.
	Membrane fluidity.
	Intercellular exchange of organelles.
Proteins	Intracellular diffusion measurements.
	Rate and direction of movement of target proteins.
	Assembling–disassembling of cytoskeleton, nucleoli, etc.
	Protein passing through pathways of posttranslation modifications (Golgi, ER) and degradation (endosomes).
	Tracking viruses within a host.
	Intercellular exchange of proteins.

to activate the whole pool of KFP1. Background fluorescence of nonactivated KFP1 can be additionally decreased by quenching blue light.

None of the photoactivatable proteins reported are perfect, and their advantages and disadvantages are marked green and red in Table 1. PA-GFP is a monomeric protein, while Kaede and KFP1 are tetramers. Thus, only PA-GFP can be used safely in fusions with other proteins. The successful application of PA-GFP to protein tracking has been reported recently (Tulu *et al*., 2003). Tetrameric state of Kaede and KFP1 can impede proper folding and/or functioning of tagged proteins. So, the main area of Kaede and KFP1 applications lies in cell and organelle photolabeling. Considering the required wavelengths of activation light, one can see that KFP1 requires well-tolerated green light, while both PA-GFP and Kaede need much more phototoxic UV-violet light. Another advantage of KFP1 is that it "occupies" only one (red) fluorescence color allowing multicolor labeling together with other GFP-like proteins, for example, PA-GFP or any other GFP variant. Kaede demonstrates the highest contrast due to a simultaneous decrease in green and an increase in red fluorescence. However, Kaede engages two fluorescent colors, and thus it cannot be used simultaneously with GFP. Finally, red photoactivatable proteins, Kaede and KFP1, have the general advantages of red dyes, which suffer less interference from background cellular autofluorescence, and which penetrate deeper through animal tissues compared to shorter wavelength emission.

Development of novel monomeric photoactivatable proteins of different colors requiring activating light of different wavelengths remains one of the most urgent tasks. Red and far-red proteins that can be activated by low phototoxic orange-red or multiphoton infrared light are of special interest. A useful set of photoactivatable GFP-like proteins will extend the application area for noninvasive optical imaging methods to investigate living objects.

7. Photoactivatable fluorescent proteins in nature

Most photoactivatable proteins described in this review are natural or at least based on natural properties of wild-type proteins found in Anthozoa and Hydrozoa species. For example, a natural protein Kaede rapidly converts to red fluorescent form under UV-violet light irradiation of relatively low intensity. Its photoactivation capability was found accidentally – when the protein was left near the window! KFP was first cloned from the *Anemonia sulcata* – and it is possible that photoactivation of this protein plays a functional role in the anemone. PA-GFP activation is based on the decarboxylation of the Glu222 under UV-violet light irradiation, which probably occurs in nature in different GFP-like proteins as a way of posttranslational protein modification.

Many of the GFP-like proteins probably undergo some photoactivation in natural environment within the organisms of Cnidaria and Crustacea species under intense sunlight. Since the function(s) of GFP-like proteins remain(s) unclear, it is especially difficult to speculate the role of photoactivatable proteins in living organisms. However, it is possible to assume that active and self-dependent adaptation of these proteins to sunlight allows organisms to accommodate changing

light and temperature conditions without changes of gene expression. Anyway, it makes sense to continue to search for novel photoactivatable fluorescent proteins in nature.

Specialist Review

FRET-based reporters for intracellular enzyme activity

Moritoshi Sato and Yoshio Umezawa

The University of Tokyo, Tokyo, Japan

1. Introduction

Many breakthroughs in our understanding of signal transduction, especially in complex tissues such as those found in the central nervous system, have depended on decoding the spatial and temporal dynamics of intra- and extracellular signaling biomolecules. The most generally applicable and popular techniques with a high spatial and temporal resolution include the use of optical probes. Fluorescent reporters have been developed that report local concentrations of the signaling biomolecules or ions of interest by alternations in the amplitude or wavelength distribution of their excitation or emission spectra. For instance, synthetic fluorescent Ca^{2+} reporters including Fura-2, Indo-1, and Quin-2 contributed to reveal intracellular dynamics of Ca^{2+}, such as Ca^{2+} waves and Ca^{2+} oscillations, under a fluorescence microscope (Tsien, 1994). Also, synthetic fluorescent reporters were recently developed for other ions and small biomolecules such as Zn^{2+} and nitric oxide (Walkup and Imperiali, 1997; Kojima *et al*., 1998). Green fluorescent protein (GFP) was recently cloned from the jellyfish *Aequorea victoria* and used for genetically labeling the signaling proteins, instead of conventional synthetic dyes such as fluorescein and rhodamine (Tsien, 1998). This genetic labeling method of cellular proteins facilitated direct observation of the proteins not only in living cells but also in tissues and organs from transgenic animals expressing fusion proteins of GFP and the proteins of interest. Mutagenesis studies further generated different-colored GFP variants, such as blue fluorescent proterin (BFP), cyan fluorescent protein (CFP) and yellow fluorescent protein (YFP) (Tsien, 1998). This GFP technology has accelerated the generation of fluorescent reporters for signaling molecules, because pairs of these different-colored GFP variants respectively act as a donor and acceptor for fluorescence resonance energy transfer (FRET) (Miyawaki and Tsien, 2000). So far, we and other groups have developed genetically encoded fluorescent reporters for visualizing cellular key signaling species, including Ca^{2+} (Miyawaki and Tsien, 2000), cyclic AMP (Zaccolo *et al*., 1999), cyclic GMP (Sato *et al*., 2000), small G-proteins (Mochizuki *et al*., 2001). These reporters revealed novel spatio-temporal dynamics of each signaling player in living cells. Further development of fluorescent reporters for pivotal signaling processes should be an

active area of interest. In this review, we discuss fluorescent reporters for protein phosphorylation–based signal transduction and lipid second messengers.

2. Protein phosphorylation

Protein phosphorylation by intracellular kinases plays one of the most pivotal roles in signaling pathways within cells (Hunter, 2000). To reveal the biological functions of these kinases, electrophoresis, immunocytochemistry, and in vitro kinase assay have been used. However, these conventional methods do not provide enough information about the spatial and temporal dynamics of the signal transduction based on protein phosphorylation and dephosphorylation in living cells. To overcome these limitations for investigating kinase signaling, we developed genetically encoded fluorescent reporters for visualizing protein phosphorylation in living cells (Sato *et al*., 2000) (Figure 1). Using these reporters, we visualized under a fluorescence microscope when, where, and how the protein kinases are activated in single living cells.

To construct the fluorescent reporters for protein phosphorylation, a substrate domain for a protein kinase of interest is fused with a phosphorylation recognition domain via a flexible linker sequence (Figure 1). The tandem fusion unit consisting

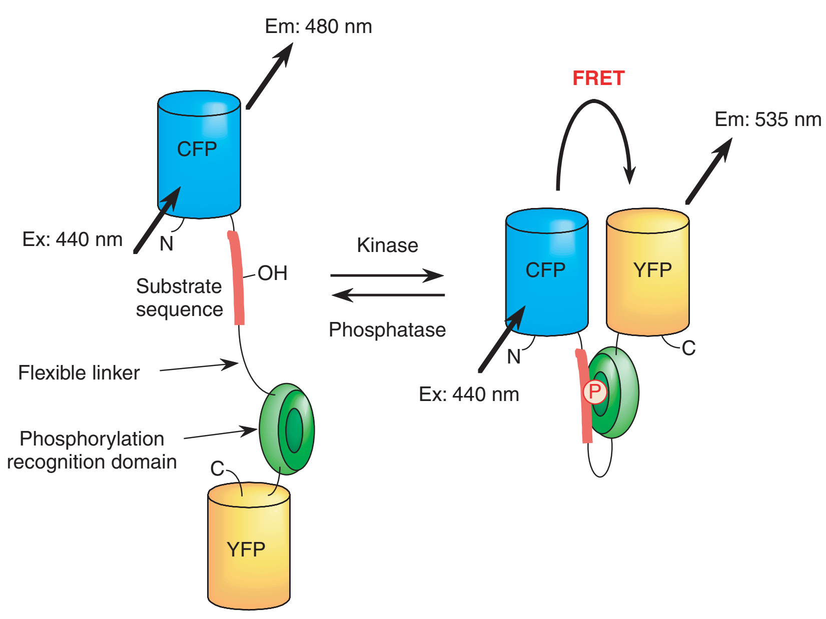

Figure 1 Principle of a fluorescent reporter for protein phosphorylation, which was named phocus. Upon phosphorylation of the substrate domain within phocus by the protein kinase, the adjacent phosphorylation recognition domain binds with the phosphorylated substrate domain, which changes the efficiency of FRET between the GFP mutants within phocus. By tethering a localization domain with phocus, the phocus can be localized in the specific intracellular locus of interest to visualize the local phosphorylation event there. Abbreviations: CFP: cyan fluorescent protein; YFP: yellow fluorescent protein; P in an open circle, the phosphorylated residue

of the substrate domain, linker sequence and phosphorylation recognition domain, is sandwiched with two different color fluorescent proteins, CFP and YFP, which serve as the donor and acceptor fluorophores for FRET (Figure 1). As a result of phosphorylation of the substrate domain and subsequent binding of the phosphorylated substrate domain with the adjacent phosphorylation recognition domain, FRET is induced between the two fluorescent units, which elicits the phosphorylation-dependent changes in fluorescence emission ratios of the donor and acceptor fluorophores (Figure 1). Upon activation of phosphatases, the phosphorylated substrate domain is dephosphorylated and the FRET signal is decreased (Figure 1). We named this reporter "phocus" (a fluorescent reporter for protein phosphorylation that can be custom-made). By using suitable substrate and phosphorylation recognition domains, we have developed a large number of phocuses for several key protein kinases including a receptor tyrosine kinase, the insulin receptor (Sato *et al*., 2002) and a serine/threonine protein kinase, Akt/PKB (Sasaki *et al*., 2003) (Table 1). In addition, substrates for protein kinases and phosphatases can be targeted to specific subcellular compartments including mitochondria, the Golgi apparatus, nucleus, and plasma membrane in living cells, which are thought to be critical for specific signal transduction in the respective intracellular loci. Thus, we further tailored our phocuses to analyze the phosphorylation events in such particular locations in single living cells (Table 1).

2.1. A phocus for imaging phosphorylation by insulin receptor

IRS-1 is one of the major substrates of insulin receptor. It contains a Peckstrin Homology (PH) domain and a phosphotyrosine binding (PTB) domain at its N-terminal end. The PH domain binds to phosphoinositides in the plasma membrane, and the PTB domain binds to the juxta-membrane domain of insulin receptor, which is tyrosine-phosphorylated almost immediately after insulin binding to the receptor. Thus, the concentration of IRS-1 is thought to be increased

Table 1 Detailed information on composition of each fluorescent indicator for protein phosphorylation and on each location to be directed in single living cells

Kinase	Indicator	Localization domain	Localization	Substrate domain	Phosphorylation recognition domain
Insulin receptor (tyrosine kinase)	Phocus-2pp	PH-PTB domain from IRS-1	Cytosol, nucleus, and membrane ruffles including insulin receptor	ETGTEEYMKMDLG	$p85\alpha_{330-429}$

	Bad-Aktus	$Tom20_{1-33}$	Mitochondria	RGRSRSAP	$14\text{-}3\text{-}3\eta_{82-235}$

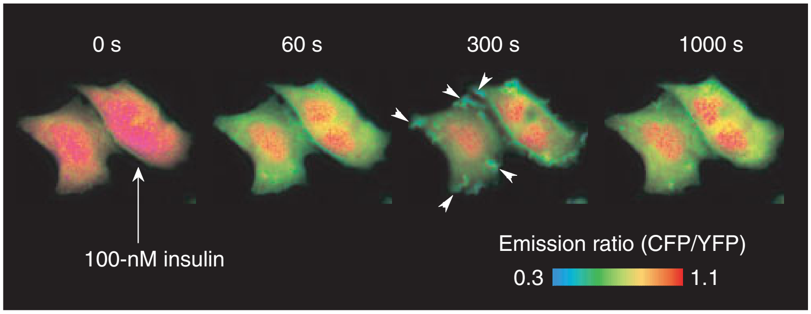

Figure 2 Fluorescence imaging with phocus-2pp upon insulin stimulation. Pseudocolor images of the CFP/YFP emission ratio are shown before (time 0 s) and at 60, 300, and 1000 s after the addition of 100-nM insulin at 25 °C, obtained from the CHO-IR cells expressing phocus-2pp. Insulin-induced accumulation of phocus-2pp at the membrane ruffles is indicated by white arrows in the image at 300 s

around the insulin receptor at the plasma membrane upon insulin stimulation. These PH and PTB domains were fused with phocus, named phocus-2pp, to locate the phocus around the insulin receptor like IRS-1 and to measure the local phosphorylation event there (Table 1). When phocus-2pp was expressed in CHO-IR cells, fluorescence was observed throughout the cells (Figure 2, time 0 s). Upon insulin stimulation, the CFP/YFP emission ratio expressed with pseudocolor was decreased in the cytosol owing to phosphorylation-induced FRET from CFP to YFP within phocus-2pp. 300 s after insulin stimulation, membrane ruffles, in which a large amount of phocus-2pp were accumulated, appeared around the plasma membrane and disappeared in 1000 s (Figure 2). In these membrane ruffles, phocus-2pp was found to colocalize with the insulin receptor. Interestingly, in these membrane ruffles, the extent of phocus-2pp phosphorylation was visualized to be ∼2-fold greater than that in the cytosol. This difference in phosphorylation levels between intracellular loci could be due to different balance of kinase and phosphatase activities between these intracellular loci. Phocus-2pp should contribute to uncovering the biological significance of such characteristic domains for tyrosine kinase signaling in membrane ruffles with high spatial and temporal resolution.

2.2. *Aktus for imaging phosphorylation by Akt/PKB*

Akt/PKB is a serine/threonine kinase that regulates a variety of cellular responses, such as cell proliferation, cell survival, and angiogenesis (Marte and Downward, 1997). To provide information on the spatial and temporal dynamics of the Akt activity in single living cells, we have developed a genetically encoded fluorescent reporter for Akt, named *Aktus* (Sasaki *et al*., 2003). Almost all Akt substrates are localized to subcellular regions. For example, eNOS (Fulton *et al*., 2001), which mediates a vasodilatory effect by nitric oxide production, is predominantly localized to the Golgi apparatus, while Bad (Chao and Korsmeyer, 1998), which is related to apoptosis promotion, is present in mitochondrial outer membranes. By

Table 2 Differential subcellular localization of activated Akt between cellular stimuli

	Cytosol[a]	Golgi[b]	Mitochondria[c]

[b]Measured with eNOS-Aktus.
[c]Measured with Bad-Aktus.

fusing the Aktus with the respectively subcellular localization domains within the eNOS and Bad, eNOS-Aktus and Bad-Aktus, which are respectively localized to the Golgi apparatus and mitochondrial outer membrane, were developed as shown in Table 1 and compared with the cytosolic diffusible reporter, Aktus (Sasaki *et al*., 2003). We have shown that in vascular endothelial cells, the Golgi-localized reporter, eNOS-Aktus, was phosphorylated upon stimulation with insulin and with 17β-estradiol, whereas the mitochondria-localized Bad-Aktus was phosphorylated in response to 17β-estradiol but not by insulin (Table 2). On the other hand, the diffusible reporter, Aktus, was not efficiently phosphorylated either upon insulin or 17β-estradiol stimulation (Table 2). These results suggest that activated Akt is localized to various subcellular compartments including the Golgi apparatus and/or mitochondria rather than diffusing throughout the cytosol, thereby efficiently phosphorylating its substrate proteins. Our observations with the mitochondria-localized reporter suggest that localization of activated Akt to mitochondria is triggered by 17β-estradiol but not by insulin. The present reporters and their applications are thus expected to contribute to the studies of a whole range of dynamics of activated Akt in living cells.

To summarize, we have developed a method for visualizing protein phosphorylation–based signal transduction in the living cells, which was herein exemplified for insulin receptor and Akt signaling pathways. The present method is also applicable for certain other protein kinases of interest by changing the substrate sequence, phosphorylation recognition domain, and localization domain. We suggest the use of substrate sequences selectively phosphorylated by kinases of interest to rule out the possibility that such tailor-made reporters are also phosphorylated by other kinases. Our method is advantageous not only for imaging kinase signaling in single live cells and tissues with high spatial and temporal resolution but also for multicell analysis aimed at high-throughput screening to identify pharmaceuticals that regulate kinase and phosphatase activities.

3. Lipid second messengers

Phosphatidylinositol-3,4,5-triphosphate (PIP_3), one of the lipid second messengers, regulates diverse cellular functions including cell proliferation and apoptosis, and any dysregulation in its production can lead to major diseases such as diabetes and cancer (Czech, 2000). This PIP_3 is generated at the cellular membrane by

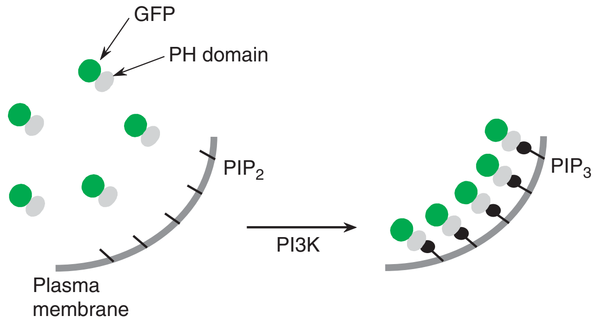

Figure 3 A conventional method for imaging PIP_3 accumulation at the plasma membrane. This reporter is a fusion protein of GFP and a PH domain that specifically recognizes PIP_3

phosphoinositide 3-kinases (PI3Ks), and recruits and activates its binding proteins at the cellular membranes, including Akt, PDK1, Btk, and GRP1 (Cantley, 2002). However, little is known about exactly when, where, and how PIP_3 is produced. Recently, fusion proteins of GFP and PIP_3-binding domains derived from Btk, GRP1, ARNO, or Akt have been reported as reporters for PIP_3 accumulation in the cellular membrane, in which the translocation of the fusion proteins from the cytosol to the membrane has been explained to reflect the PIP_3 accumulation (Varnai *et al*., 1999; Venkateswarlu *et al*., 1998a,b; Watton and Downward, 1999) (Figure 3). However, several factors such as membrane ruffles and changes in the cell shape, which are frequently observed during fluorescence imaging experiments, affect the fluorescence intensity change in the region of interest in a PIP_3-independent manner and cause serious artifacts. Moreover, it is difficult with these fluorescent fusion proteins to distinguish to which membranes the fusion proteins are translocated in the cell. To overcome these limitations, we have developed fluorescent reporters for PIP_3, based on FRET (Sato *et al*., 2003) (Figure 4). These novel PIP_3 reporters are composed of two different-colored mutants of GFP and a PIP_3-binding domain, and the PIP_3 level was observed by dual-emission ratio imaging, thereby allowed stable observation of PIP_3 without suffering from the artifacts described above. To construct the fluorescent reporters for PIP_3, a PH domain of GRP1, which selectively binds with PIP_3, is sandwiched between cyan (CFP) and yellow (YFP) variants of *Aequorea* GFP, via rigid α-helical linkers, consisting of repeated EAAAR sequences (Figure 4). Within one of the rigid linkers, a single diglycine motif is introduced as a hinge. This chimeric reporter protein is tethered with the membrane by fusing with a membrane localization sequence (MLS) via the rigid α-helical linker (Figure 4). When PIP_3 is produced at the membrane upon PI3K activation, the PH domain binds to the PIP_3, and a significant conformational change in the reporter protein quickly occurs around the flexible diglycine motif introduced in the rigid α-helical linker (Figure 4). This flip-flop-type conformational change of the reporter protein causes intramolecular FRET from CFP to YFP, which underlies the detection of PIP_3 dynamics at the cellular membrane (Figure 4). We named this reporter “fllip” (a fluorescent reporter for a lipid second messenger that can be tailor-made) (Sato *et al*., 2003).

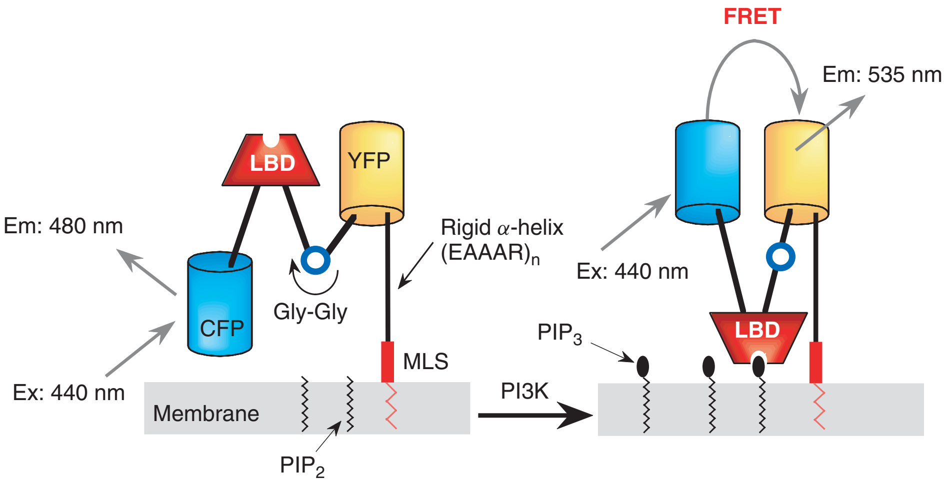

Figure 4 Principle of fllip for visualizing PIP_3. Upon binding of PIP_3 with the PH domain within fllip, a filp-flop-type conformational change of fllip takes place, which changes the efficiency of FRET from CFP to YFP. Abbreviations: LBD: lipid binding domain; MLS: membrane localization sequence

Fllip can be located to particular membrane surfaces of interest by connecting appropriate MLSs, such as lipidation sequences and transmembrane sequences. For example, using the CAAX box motif of N-Ras as the MLS yields a reporter for PIP_3 at the plasma membrane (fllip-pm). Using the mutated CAAX box sequence of N-Ras, in which the cysteine 181 was replaced with a serine, fllip was localized at the endomembranes to monitor the PIP_3 level there (fllip-em).

Using the fllip variants that exhibit each specific subcellular distribution, we revealed spatio-temporal regulations of the PIP_3 production in single living cells. We found that in response to ligand stimuli, PIP_3 was increased to a large extent at the endomembranes rather than at the plasma membrane (Figure 5). In addition, we revealed that this PIP_3 increase at the endomembranes was due to its *in situ* production at the endomembranes triggered by endocytosed receptor tyrosine kinases. The demonstration of PIP_3 production through receptor endocytosis addresses a long-lasting question about how its downstream signaling

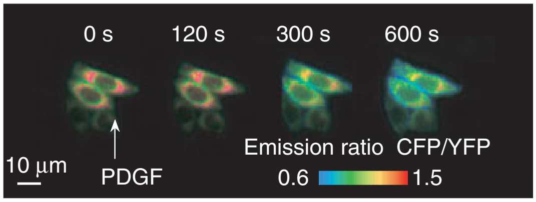

Figure 5 Response of fllip-em to PIP_3 at the endomembranes upon PDGF stimulation. Figure shows pseudocolor images of the CFP/YFP emission ratio before (time 0 s) and at 120, 300, 600 s after the addition of 50 ng mL^{-1} PDGF, obtained from the CHO-PDGFR cells expressing fllip-em. Blue shift in the CFP/YFP emission ratio indicates the production of PIP_3 at the endomembranes

pathways including Akt are activated at intracellular compartments remote from the plasma membrane, such as the Golgi and mitochondria.

From a methodological viewpoint, it should be mentioned that the present fllips, which are genetically encoded fluorescent reporters, have general applicability for other lipid second messengers as well. Fllips have two key sections, the PH domain and MLS, that can be tailor-made. Lipid second messengers other than PIP_3, such as diacylglycerol (Zhang *et al*., 1995) and phosphatidylinositol-3-phosphate (Misra *et al*., 2001), could be selectively detected by using appropriate binding domains for respective lipid messengers instead of the PH domain. Also, by connecting each specific MLS, fllips could be directed not only to the plasma membrane and endomembranes but also to other organelle membranes, such as the inner nuclear membrane and the outer membrane of mitochondria.

Specialist Review

Quantitative EM techniques

John M. Lucocq
School of Life Sciences, University of Dundee, Dundee, UK

1. Introduction

This article examines strategies for quantification from sectioned biological material at the electron microscope (EM) level. Recently there has been increasing demand for rigorous quantification and for linking morphological results with physiological and biochemical data. To achieve this it has been essential to develop a body of methods that allows accurate, unbiased, and efficient estimation of thin section and 3D quantities. This article describes current approaches to quantitation of both structure and immunolabeling. Sectioning is a powerful tool for revealing the internal structure of cells and tissue. At the ultrastructural level it provides samples that are thin enough for clear display of internal cell components and presents the opportunity to sample 3D specimens appropriately. Here the focus is exclusively on quantification on thin sections of biological material.

Structural display is the sine qua non of good quantitative EM because one cannot quantify what cannot be seen. Therefore optimal specimen preparation and structure contrasting lie at the heart of all successful quantification regimes; however, these lie outside the scope of this article (see Griffiths, 1993; Liou *et al*., 1996). Methods for molecular contrasting at the EM are also now well established and these range from the less popular preembedding approaches, which use either particulate or enzyme-based methods producing electron dense enzyme reactions to the more widely used on-section labeling that utilizes particulate markers. Particulate markers have the inherent advantage of being countable and have been proved to yield a signal that can report on antigen concentration. Currently the most important particular marker system in widespread use is the colloidal gold (Lucocq, 1993a) but other methods such as quantum dots (Giepmans *et al*., 2005) are showing promise of improved labeling quality.

2. The basics of sampling

Using sections to provide readouts of structure or immunolabel introduces the problem of sampling (Lucocq, 1993b). All sections, whether they are immunolabeled or used for structural quantitation, are small samples ultimately derived from an animal/experiment, culture, organ, tissue, cell, or organelle. It is

important that the information contained in the sections used is representative of the "experimental universe" from which they are drawn, whether this is a set of animals or cell cultures. To ensure this representation is fair, sampling must be strictly nonselective and so simple uniform random sampling is the mainstay of all EM quantitative approaches. In fact this is a minimum requirement at all levels of the sampling hierarchy (animals/experiments, dishes, blocks, sections, EM grids, EM grid holes; see Figure 1). In heterogeneous biological systems simple random sampling may not always be the most efficient strategy and can be modified to improve the accuracy of results obtained from doing a particular amount of work. The best-known modification is *systematic random sampling*, in which a random start point ensures unbiasedness, and subsequent samples are spaced in a pattern at regular intervals through the organ, specimen, block, or section (see Figure 1). When biological samples are heterogeneous, systematic random sampling is usually more efficient, partly because it spreads-out "measurements" to sense local variations. By comparison, simple random samples may tend to cluster or become dispersed and thereby over- and underrepresent certain regions. Systematic random sampling is also simpler to set up than simple random sampling. As we shall see, depending on the intended readout it is almost always necessary to randomize the position of the section within the specimen of interest; for some parameters, it may also be important to randomize orientation as well.

3. Immunolabel quantitation

Because labeling systems are applied to sections that produce essentially 2D images of structure, this represents the simplest system to illustrate principles of quantification. After the introduction of the particulate markers, many studies used purely qualitative assessment of labeling. However, assessing small changes in labeling intensity or amounts of dispersed label is difficult by eye and comparisons between conditions, or between different compartments, demanded unbiased quantitative measures. Sectioning opens up cellular compartments and makes them available to the immunogold labeling reagents that are applied to the sections. The random placement of sections at the lower end of a random sampling-based hierarchy therefore ensures that the components of compartments/structures in the animal/cell line have similar probability of encountering the reagents. This is an important advantage over permeabilization techniques in which penetration of the reagents is at the mercy of both structural variables and permeabilization conditions that are difficult to control (Griffiths, 1993).

In an ideal world there would be a direct and proportionate relationship between particle labeling and protein antigens irrespective of their location in the cell, but in reality the relationship is influenced by the structural context in which the antigen is sitting and other factors such as modification of the antigen or the characteristics of the antibody probes. Thus, the number of particles labeling each protein (often termed the *labeling efficiency*) can vary from compartment to compartment or from structure to structure (Lucocq, 1994; Griffiths and Hoppeler, 1986). Important work from the Utrecht group (e.g., Posthuma *et al*., 1988) determined that variation is due to different penetration of labeling reagents and sought to eliminate these

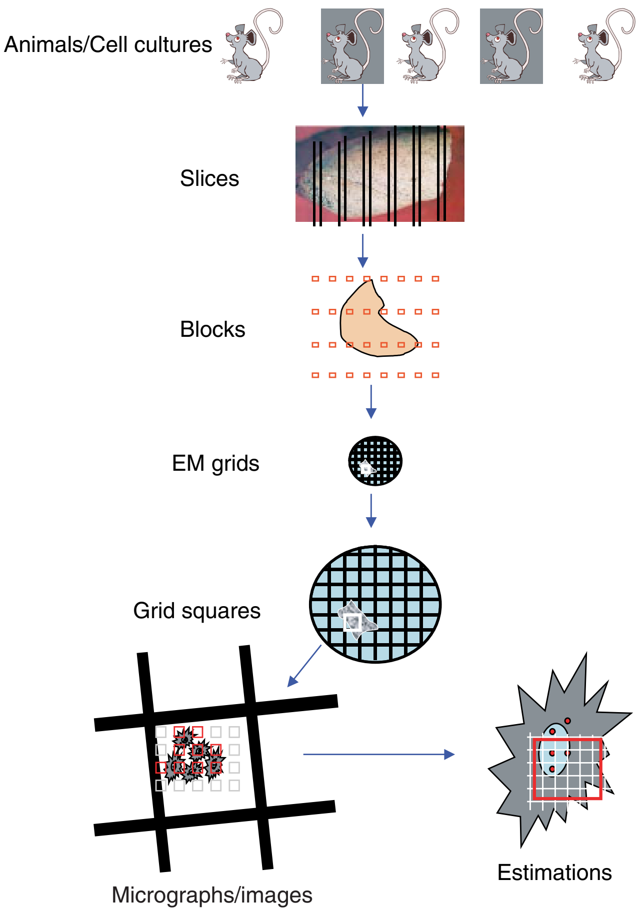

Figure 1 Sampling hierarchy. Quantitative estimations using electron microscopy are carried out on microscope viewing-screen images or micrographs of thin-sectioned material. These represent very small samples of the organ/tissue/cells from individual animals or cell cultures. The problem faced is how to sample slices, blocks, EM grids, EM grid holes, and micrographs, so that the estimations contain fair estimates of the parameters required. An absolute necessity is random selection of the items at each level of the sampling hierarchy. Increases in efficiency can be obtained from a systematic array of samples that is applied randomly. In the case shown here the organ has been systematically sampled first with slices and then as EM blocks. Sections from these blocks are sampled at a randomly selected EM grid hole and systematically spaced micrograph sections taken. Finally a randomly positioned geometric probe with systematic lattice structure is applied to each micrograph (see text for details and discussion of cases in which randomization of orientation is also a requirement). In general, studies have found that higher levels of the hierarchy are the major contributors to the overall variance and it is advisable to study a minimum of three and preferably five animals/cultures/experiments. Experience has shown that 10–20 micrographs and 100–200 events at the estimation stage may be sufficient to reduce the contribution from this level to a minimum. At the intermediate levels of the hierarachy, the number required will be determined by the heterogeneity of the specimen

differences by embedding fixed cells or tissues in either polyacrylamide or Lowicryl resins. As things stand, most workers accept the underlying variation in labeling efficiency between compartments. It is worth noting also that labeling efficiency over the same compartment take out may remain constant from experiment to experiment so that labeling intensity may correlate rather well with local changes in the concentration of antigen.

3.1. Estimation of labeling (antigen) distribution

Estimating the distribution of particulate labeling is of fundamental importance in quantitative EM. Mapping studies enable informed judgements about the antigen distribution and are a good way of identifying the compartments or structures that contain pools of antigen. It is important to realize that while the distribution of labeling over a number of compartments/structures may be relatively insensitive to overall changes in the intensity of the labeling signal, it may be biased by focal changes in labeling intensities in ways that are difficult to interpret (see discussion of labeling density below).

Strategies for estimation of labeling distribution depend on obtaining a systematic sample from a representative labelled section. As described above, random sampling (simple or systematic) of animals/experiments, dishes, and blocks with random positioning of the section within the blocks ensures fair representation of different elements in the sampling hierarchy (Figure 1; note that the issue of how section orientation affects labeling efficiency has not been addressed systematically and it may be pertinent to include measures that randomize orientation as well as position in labeling studies (see below)). When thin sections are mounted on EM grids they may be of variable quality or may be so extensive as to preclude sampling the whole section area. Under these conditions smaller regions of the section can be selected by random (or systematic random) selection of EM grid holes containing sections of interest. It is worth reiterating the adage that one cannot quantify what cannot be seen and so adequate contrasting of sections of the appropriate thickness to reveal the structure of interest is important.

The most efficient way of sampling a selected labeled section (or more limited area of the section) is to obtain a systematic random sample and this can be achieved in a number of ways. In one approach, the selected section area can be scanned in strips at the electron microscope (Figure 2a), at a magnification at which the particulate marker and the structures of interest can be identified. Initially the magnification selected should be the lowest that allows both structures/compartments and particulate marker to be clearly seen as this maximizes the sample size. The strips are defined by translocation of the section under the screen and 10–20 of them are systematically spaced (with a random start) and cover the whole of the selected area (see Lucocq *et al*., 2004). A second approach is to take micrographs at systematic random locations across the selected area of the section (Figure 2b). Again the magnification used should be the minimum that allows both particles and structure to be visualized. The number of compartments assessed would depend on the underlying biology and

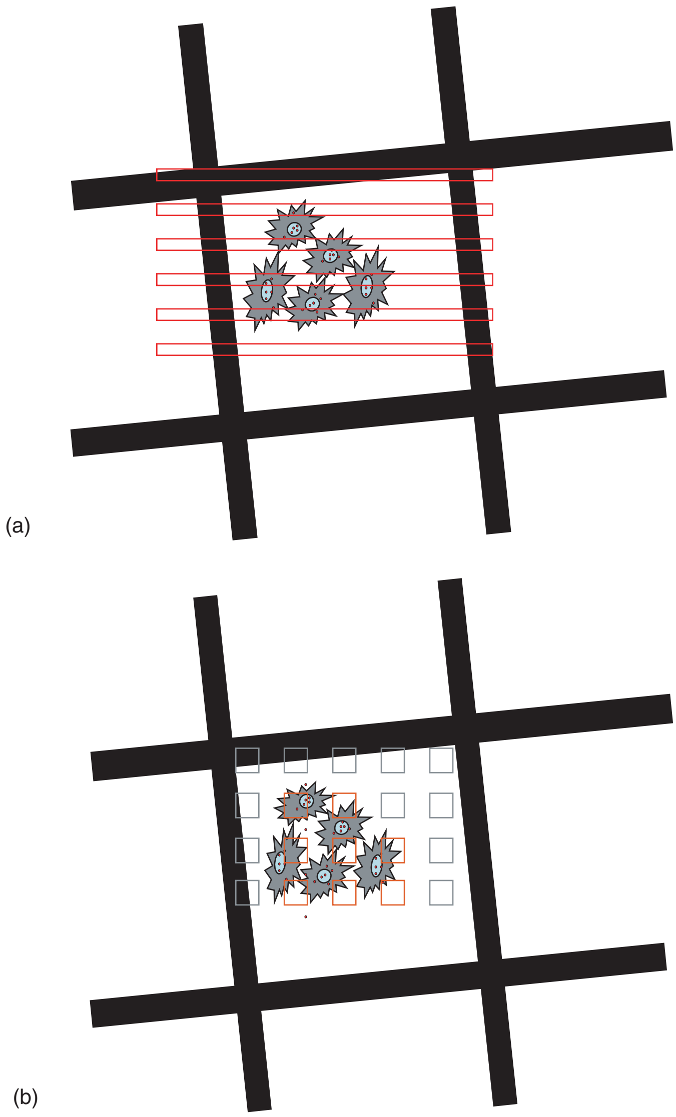

Figure 2 Labeling distribution. Systematic sampling of particulate immunolabeling can be achieved using all available sections on an EM grid. But usually an area of interest such as an EM grid hole (or holes) containing optimally contrasted section(s) is selected at random. In the scanning method (a) this area of interest is translocated under the viewing screen to create systematically spaced strips– initially at a magnification sufficient to visualize both the labeling and structures of interest. The uppermost corner of the grid hole can be used as a randomly placed marker to position the scans. In the micrograph method, (b) images (containing relevant cell compartments/labeling) are recorded at systematically spaced locations, again using the uppermost corner of the EM grid hole as a marker of random position

the goals of the experiment (see Mayhew *et al*., 2002; Griffiths *et al*., 2001). Particles are counted and assigned to compartments during the scanning procedure and approximately 200 particles per grid are enough to describe the distribution over 10–15 compartments (Lucocq *et al*., 2004). If a more precise value of the labeling fraction in one particular compartment is required, then 100–200 particles should be examined over that individual compartment (Lucocq *et al*., 2004). This level of sampling has also been found to be sufficient in many stereological studies. With these guidelines in mind it may be pertinent at some stage of a study to increase or decrease the total number of sampled particles. Increases in particle numbers counted may be achieved simply by increasing sample size (scan or micrographs), while decreases follow from increasing magnification used in the scanning approach or by decreasing the quadrat size on micrographs. It is generally advisable to apply unbiased counting rules to the scanning strips or to quadrats used for counting on micrographs, especially when the size of the gold particles becomes significant relative to the quadrat (>100th of the quadrat size; Lucocq, 1994).

Recently, powerful methods for comparison of the raw particle count distribution between groups have been introduced (Mayhew *et al*., 2004). This type of analysis is facilitated by the use of contingency table analysis with statistical degrees of freedom for chi-squared values being determined by the number of compartment and number of experimental groups of cells (see Mayhew *et al*., 2004 for discussion and details). The method enables identification of compartments/structures in which the major between-group differences reside.

3.2. Estimation of labeling density

The local intensity of particulate immunolabeling reflects the local concentration of a component antigen (Griffiths, 1993) and is therefore a biochemically relevant quantity for that compartment/structure. The labeling intensity can be found by relating label to the size of a structure/compartment, and in the classical approach, labeling density is related to the absolute size of profiles displayed on the ultrathin sections. Profile sizes can be estimated by interactions of geometrical probes such as points or lines as systematic test grids (see Figure 3a). Points are used to estimate organelle area and lines to estimate profile length (usually membranes) (see Griffiths, 1993; Lucocq, 1994). With the number of probe hits, the spacing of the probes in the grid and magnification, a simple formula converts the counts to areas or lengths from which the absolute density values can be estimated (see Figure 3). Notice that to ensure unbiasedness of the estimates, the grid of geometric probes is applied as a systematic series of points or lines. For unbiased estimations, there is a requirement for random placement of points (for area estimation) or random placement *and* orientation of lines (for profile length estimation); and a course for random sampling throughout the hierarchy (as yet the need for random orientation in 3D has not been systematically investigated; see discussion below for surface estimation). Traditionally when the grid is applied to micrographs/digital camera images, the density is reported per square micron or density per micron length of membrane, thereby allowing

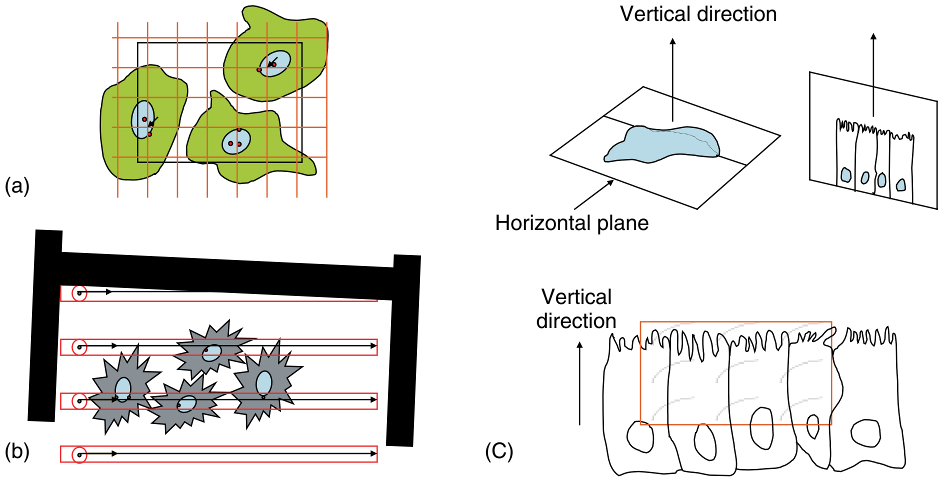

Figure 3 Labeling density, volume, and surface density. Labeling density can be expressed as labeling per unit profile area or per unit length of profile. As shown in (a), the area can be estimated using point hits over the structure. The points can be defined as the corners of lattice squares and the profile area, A, can be computed from the product of area associated with each point on the lattice (a/p) and the total number of point hits (ΣP) on the stucture. Here, there are two point hits (arrows) over the nucleoplasm and the number of labeling particles is two. Random placement of the lattice relative to the specimen is a requirement. The profile length of nuclear envelope (here represented by a single membrane trace) can be estimated from the number of intersections (I) of the envelope with lattice lines (in this case 9), which should be randomly oriented and positioned relative to the membrane profiles. Trace length is computed using $(4/\pi)Id$ where d is the real distance between the lines ($(2/\pi)Id$ is the formula if only one set of parallel lines are used). Assignment of gold particles to membranes (in this case 3) is decided on the basis of acceptance zones within which dispersion of label is considered to be possible – for example, two particle widths for 10-nm diameter particles (se Griffiths, 1989a). As described in the text, labeling may be related to point counts or intersections without conversion to absolute units. Relating labeling to intersection counts can also be achieved by an adaptation of the scanning approach in which gold particle counts are related to intersections of structures with a scanning line defined as a feature located in the EM viewing screen moves relative to the section (b).

The systematic lattice illustrated in (a) can also be used to estimate volume and surface density in 3D stereologically. For unbiased estimation of volume density, the lattice is randomly placed inside the specimen by ensuring random selection/placement at all levels in the hierarchy. The fraction of points that fall over the structure of interest relative to a reference space, reports on the volume density of the structure in the reference space.

Intersection of structures with lattice lines (I) enables estimation of the surface density using the formula $2I/L$ where L is the total line length applied to the specimen. Either the lines or the specimen must be randomly placed *and* oriented in space for unbiased estimations (see text for some details on generating isotropic lines). (c) Illustrates one method of generating isotropic uniform random lines in space. A recognizable horizontal plane (in this case the base of a columnar cell sheet) enables a vertical direction to be identified. A section along the vertical direction is taken in uniform random position and at random angle of rotation around the vertical axis. On this section plane, isotropic lines can be represented by sine weighted lines, for example, cycloid arcs usually applied as a systematic lattice (test system in red quadrat of figure). Intersections of linear profiles with these test lines allow surface density to be estimated according to the formula $2I/L$ (see Baddeley *et al*., 1987; Howard and Reed, 1997 for details)

interpretation and comparison with other studies. This type of density information can also be used in combination with section thickness measurements to estimate density of labeling over structures in 3D (see, e.g., Griffiths and Hoppeler, 1984).

More recently, for certain comparative purposes, particulate labeling has been related to point or intersection counts without "converting" to absolute area or

length units (see Figure 3). Density can be expressed as gold particles per point or intersection (Watt *et al*., 2002; 2004; Mayhew *et al*., 2002) and this index of labeling intensity has been used to test for preferential labeling over individual or groups of compartments. In one approach, the labeling densities are compared to those obtained if the existing gold labeling were randomly spread over all compartments to provide a relative labeling index (RLI; see Mayhew *et al*., 1996, 1999). The intensity data can be obtained on micrographs or from scanning in strips at the electron microscope using the viewing screen in which a feature acts to trace a scanning line for intersection counting (see Figure 3b). This type of approach cannot at present be applied to both organelle and membrane surfaces simultaneously.

4. Structure quantification

Analysis of structural parameters in 3D from sections requires specifically designed stereology that employs sampling with geometrical probes. The geometrical probes are generally applied to sections as systematic arrays of points, lines, planes, or brick-shaped volumes with strict rules for multistage random sampling animals, cells, blocks, sections, and micrographs. Simple formulae convert the counts into 3D quantities. As a rule of thumb the dimensions of the probe and the parameter to be estimated must add up to at least three, for example, points (0D) can only be used for volume estimation (3D) and lines (1D) but not points (0D) may be used to estimate surface (2D).

4.1. Volume fraction and surface density

Volume fraction and surface density are simply measures of the concentration of volume or surface inside the volume of some reference structure (see Figure 3a; for reasons of clarity and simplicity, length density estimation is not dealt with here (see Howard and Reed, 1998 for details). Volume fraction can be estimated using an array of points that are placed at a random location within a specimen. The fraction of points that fall on a structure relative to a reference space/structure is an estimate of the fraction occupied by the structure of interest. This is an extension from the principle outlined by Delesse (1847); see also Thompson, 1930), which states that the fractional area displayed by a structure reports on the fraction of the reference space occupied by that structure. The random/systematic random positioning of the points on the section again depends on correct sampling throughout the hierarchy and is employed down to the level of the section and the systematic array probes applied as a grid to the micrograph (Figure 3a). The orientation of the specimen can be arbitrary. Importantly, the readout is a ratio and is therefore sensitive to changes in volume of both the structure and the reference space. It is therefore advisable to have information on the size of the reference space (see below), or at least its stability. Once the reference space volume is known, then the absolute volume of the structure inside that space can be computed easily from the product of the volume fraction and the reference space volume. Volume fraction has been

one of the most used estimators in electron microscopy but is less often combined with reference space volume estimation.

Surface density is usually estimated in a volume. In cell biology, this might represent the packing density of nuclear membrane in the cytoplasm or mitochondrial cristae within mitochondria. Again caution is required in interpreting the readout ratio and knowledge of the reference space size enables absolute values for surface to be estimated from the product of surface density and reference volume. The estimates are most often made using systematic arrays of line probes that are randomly positioned and randomly oriented in 3D space, relative to the specimen (Figure 3b). A number of strategies have been developed to ensure randomness of orientation (isotropy) of probe or specimen. These include embedding the specimen in an isotropic sphere, which is rolled before embedment (the disector; Nyengaard and Gundersen, 1992); dicing tissue/cell pellets and allowing them to settle haphazardly (which is less rigorous; Stringer *et al*., 1982); and making two successive positioned oriented sections through a structure (the orientator; Mattfeldt *et al*., 1990). Finally, a powerful way to generate isotropic lines in space is to orient sections in a fixed direction vertical to an identifiable horizontal plane associated with the object, and then generate sine weighted isotropic lines on the sections (vertical section method; Baddeley *et al*., 1986; Michel and Cruz-Orive, 1988; see Figure 3c). This elegant solution allows orientation of sections along specific directions that display features of cell organization such as polarity and is well suited to surface estimation in cell monolayers sectioned in a direction perpendicular to the culture dish. Irrespective of how the isotropy is generated, the number of intersections of lines with the surface features of interest can be easily converted into a surface density value. The product of surface density and reference volume will then provide an estimate of the total surface (see Figure 3 legend and Griffiths *et al*., 1984, 1989a,b for examples).

For both volume and surface density estimations, errors may arise when structures are small compared to the section (e.g. 50–200 nm). Peripheral grazing sections result in lost caps that decrease the number of point or line encounters and underestimate surface or volume density. On the other hand as structures become small relative to the section, they overproject their profiles into the final image and lead to overestimation of size densities. Correction factors based on model shapes for the small structures are available but these should be used under carefully controlled conditions in which the models used correspond closely to the morphology of the structure in question (Weibel and Paumgartner, 1978; Weibel, 1979).

4.2. *Reference volume*

The volume of organs, tissue components, cells, or organelles, are of interest in their own right but they also represent important reference spaces in which stereological densities can be converted into absolute values.

One of the most powerful methods for volume estimation is that devised by the seventeenth century priest Bonaventura Cavalieri who was a disciple of Galileo

(Cavalieri, 1635). This approach is well suited to EM slices that are relatively thin compared to the object (a similar principle can also be applied using sections that are relatively thick Gual-Arnau and Cruz-Orive, 1998). A series of sections through the entire object are prepared at a regular spacing with the first slice lying at a uniform random start location within the section interval. The area of the object profiles as displayed on these sections is estimated by counting point hits of a lattice grid overlaid on the object profile (Gundersen and Jensen, 1987). A simple formula converts the point counts summed over all sections into the estimated object volume (Figure 4a). Importantly, 5–10 sections are generally enough to obtain precise estimates of objects irrespective of their orientation and shape. The precision of volume estimate obtained using the Cavalieri method can be assessed as the coefficient of error (Gundersen and Jensen, 1987), which decreases as the number of sections (sampling intensity) is increased. The Cavalieri method

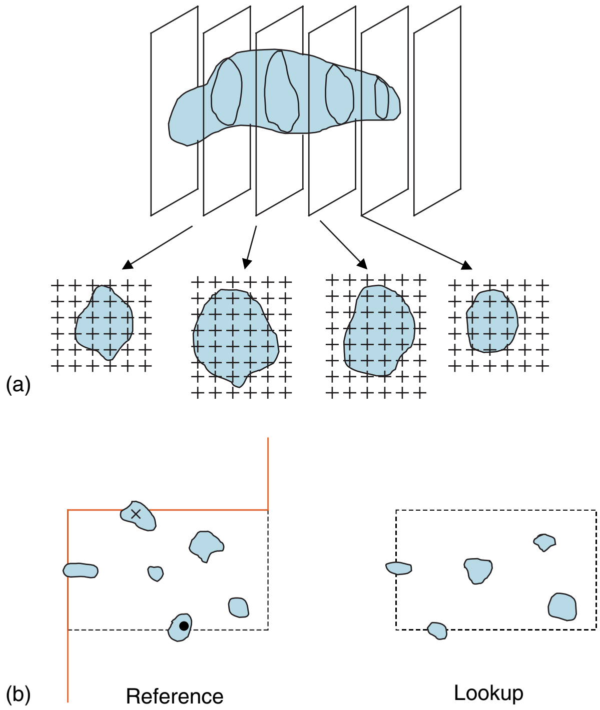

Figure 4 Volume and particle number. (a) Volume estimation using the Cavalieri sections method in EM. A systematic sample of equally spaced sections (usually 5–10) is placed at a random start location. The total profile area (A) is the product of the area associated with each point on the lattice (a/p) and the total number of point hits on the profiles (ΣP). The distance between the sections (k) is obtained from the product of the section thickness (t) and the number of sections in each interval (n_s). The volume estimate is computed from $A \times k$. (b) Principle of using a disector to count particles. In the reference section, particle profiles are selected if they are enclosed entirely in the quadrat or crossed by the dotted acceptance line. Profiles that encounter the continuous forbidden line are ignored. Selected particles that disappear in the lookup (·) section are counted. Although the particle (x) has no profile in the lookup it is not counted because its profile hits the forbidden line. See Gundersen (1988) for further details

is now widely used in light microscopy and radiology (Roberts *et al*., 2000) and in electron microscopy it is an excellent method for cell or organelle size estimation that can be combined with other estimators (Lucocq *et al*., 1989; McCullough and Lucocq, 2005). Other methods for estimating particle volume are outlined below.

4.3. Counting and sampling in 3D

The problem with sampling or counting items from 3D space with sections of cells or tissues is that the probability that a structure appears in a section is related to its size (actually its height in the direction of sectioning) and not its number. For many years quantitative biologists attempted to circumvent the problem by assuming model shapes, thereby enabling conversion of profile size distributions into particle numbers. Such model-based approaches (see Weibel, 1979 for discussion) can be inherently biased and the breakthrough in number estimation and sampling came in 1984 when Sterio reported using a two-section approach to identify and count particles in 3D space (Sterio, 1984; Mayhew and Gundersen, 1996). The essence of this approach is to sample profiles of particles displayed in a section using two-dimensional unbiased counting rules applied to a quadrat (Figure 4b) and to assess which of the selected particles are then *not* displayed in a second parallel section. This amounts to counting particle tops or edges and is particularly suited if the particles are entirely convex and therefore do not contain multiple edges. For vesicles or spheroidal or tubular structures such as nuclei or particulate mitochondria, this is not a problem. However for more complex organelles such as Golgi apparatus or interconnected mitochondria, the number of edges may be multiple and varied. The union of the sampling section (and its quadrat) with the second section (the lookup) is termed a *disector*. If disectors are placed at random or systematic random through the specimen, then the probability that a particle (nucleus, vesicle, etc.) is selected in this way is related only to its number. Once selected, this sampled structure can be further characterized. Implementation of disectors at the EM level demands accurate positioning of fields for sampling and lookup at appropriate magnifications. Important questions arise as to distance between sections in the disectors, relative to the particles in the population. Clearly the distance must be close enough to avoid missing any particles between the sections; but the method is based on comparing the profiles in sampling section and the lookup section – so it is advisable to keep the sections close enough to enable particles sectioned by both sections to be used as a reference. As a general guide disectors about one-third the height of the average particle are usually sufficient. Since the preparation of disectors for use in EM is fairly labor intensive, then each section in the disector can be used alternately as the reference and lookup to improve efficiency (see Smythe *et al*., 1989)

4.3.1. Uses of disectors

One straightforward readout from disectors is the particle density in the volume of any reference space that can be identified in the disector. The volume of this

reference space can be estimated using point counting applied to the structures displayed in the quadrat used for sampling. Interestingly the reciprocal of the particle density in particle volume turns out to be the mean number-weighted particle volume (Gundersen, 1986). The volume of particles can be also assessed using Cavalieri estimator although this requires further examination of a section stack through the entire sampled particle. At the EM level disectors have been used to sample and count coated endocytic structures (Smythe *et al*., 1989) and to characterize mitotic Golgi fragments (Lucocq *et al*., 1989).

An elegant application of the disector can be used to estimate the numerical ratio of a small structure to a larger one (the number of peroxisomes per cell nucleus, e.g., Gundersen, 1986). In a stack of sections one pair of sections is used to sample the larger structure and estimate its numerical density in a reference space. At a random location within this disector interval, a smaller disector, composed of two more closely spaced sections, is then used to sample the smaller structure and the density estimated. The ratio of the two densities reports the numerical ratio of the two structures and since the estimates are obtained using the same average section thickness, then no section thickness measurement is required and no determination of the total reference volume is required. Double disectors have been used in electron microscopy to estimate the number of coated pits per cell (Smythe *et al*., 1989), the number of Golgi fragments/vesicles per cell (Lucocq *et al*., 1989), the number of synapses (Jastrow *et al*., 1997; Mayhew 1996) and the number of gold particles per cell (Lucocq, 1992).

In the case of small structures such as vesicles there is a special case in which all structures sectioned by the ultrathin section do not have a profile in the next section. Thus the probability of finding a disappearing profile is 1. Under these conditions there may be no need for a lookup section to be used. This convenient adaptation of the disector must be used with caution and preliminary work is needed to determine the proportion of structures that are detected by one section but disappear in the next. This approach has been used to count Golgi vesicles in dividing HeLa cells (Lucocq *et al*., 1989).

4.4. Particle volume

As already discussed, the volume of structures sampled using disectors can be estimated either by using Cavalieri sections method or from the reciprocal of the particle density in the disector. However there are other methods for particle volume estimation. Unlike those just mentioned, they all require some element of isotropy. The selector (Cruz-Orive, 1987) samples particles with disectors and uses a systematic stack of sections through the particle to place sampling points within the particle volume. From these points line probes are used to estimate the volume of the particle. The distance between the sections need not be known but the orientation of the line probes must be isotropic. A refinement of the selector principle is the nucleator (Gundersen *et al*., 1988), which uses a central structure such as a nucleolus that can be sampled with constant probability as a source for the isotropic lines (Henrique *et al*., 2001). This tends to be more efficient

than the selector and uses fewer sections. Another powerful method is the rotator, which takes advantage of the Pappus theorem. This states that the product of the distance traveled by the center of gravity of a figure and its area can be used to estimate its total volume in rotation (Jensen and Gundersen, 1993). This gives the possibility of estimating the volume of an object when sections lie along a defined axis but are allowed to randomly assume any angle of rotation around this axis. This approach has been used at the EM level to estimate cell volume around the centriolar structures and the volume of the endoplasmic reticulum at different locations within mitotic HeLa cells (McCullough and Lucocq, 2005; Mironov and Mironov, 1998). Finally it is also worth mentioning the point sample intercept method (Gundersen and Jensen, 1985; Gundersen *et al*., 1988), which allows estimation of particle volume on single sections. Points are used as probes to probe particle volume and isotropic lines through these points can be used to estimate the particle volume, but this is weighted according to the volume and not number of particles.

5. 2D and 3D spatial distributions

Quantitation of total or aggregate quantities have been the main focus for EM quantitation and are often referred to as *first-order stereology*. However the statistical study of spatial distributions is of biological value in both 2D and in 3D and has been referred to as second-order stereology.

Statistical approaches for assessing the distribution of point processes in 2D have been presented by Diggle (1983) and Ripley (1981). The first-order property of such a point pattern is its intensity, expressed as number of items per unit area, whereas the second-order property is characterized, for example, by Ripley's K function, which is sensitive to the distribution of interparticle distances which can be compared to an expected number of neighbors within a distance of any point. Membrane lawns and freeze fracture techniques present 2D surfaces that can be labeled with particulate markers and the distribution of the labeling provides clues to clustering or receptors, lipids, and downstream signaling molecules. A recent application of these principles has been used to examine protein distribution at the plasma membrane (Prior *et al*., 2003). Development of 3D spatial analysis is in its infancy but the use of linear dipole probes has shown some promise in assessing the spatial distribution of volume features at the EM level (Mayhew, 1999; see also Reed and Howard, 1999). Molecular or subcellular organelle distributions have yet to be examined using this methodology.

Finally, this review covers only some of the basic principles and the reader is referred to more extensive basic texts (such as Howard and Reed, 1998) and to the International Society for Stereology (ISS) website (**http://www.stereologysociety.org/**) for further details. Advice from those experienced in this field can be invaluable to anyone embarking on a quantitative EM study.

Short Specialist Review

High content screening

D. Lansing Taylor and Kenneth A. Giuliano
Cellumen, Inc., Pittsburgh, PA, USA

1. Background

The field of "cellomics" emerged from the early success of genomics and proteomics and the term has been used interchangeably with "functional genomics" and more recently with "functional proteomics". Our definition of cellomics, as a field, is broader: "the study of the temporal and spatial activity of cells and cellular constituents that are responsible for cell functions".

High Content Screening (HCS) is a set of methods and tools that were originally created, developed, commercialized, and defined by Cellomics, Inc. in 1997 (Giuliano *et al*., 1997; Giuliano *et al*., 2003) as a platform technology for the emerging field of cellomics. In today's language, this would be called a "systems cell biology" platform. The original definition of HCS was "an automated method for analyzing arrays of cells that contain one or more fluorescent reporter molecules, where the fluorescent signals are converted into digital data and then the digital data are used to automatically make measurements of intensity and/or distribution of the fluorescent signals on or in the cells, where changes indicate a change in distribution, environment, or activity of the fluorescent reporter molecules". Variations in the original definition of HCS have evolved over the last few years as more scientists have used the technology in drug discovery and basic biomedical research. The most general definition offered to date has been "the use of biological probes in combination with imaging technologies to probe within individual cells and to screen for activity on a target at a subcellular level (Screening Review, 2004)".

HCS was conceived as a high-throughput, cell biology platform aimed at "industrializing" cell biology. The concept was analogous to the creation of automated DNA sequencing. The developers of the automated DNA sequencers that eventually allowed the human genome project to be successful in a reasonable amount of time and at a reasonable cost, did not develop all the technologies from scratch. They integrated previously developed methods of fluorescent dye tagging of nucleotides, running gels containing DNA fragments, reading the "ladders" in the gels and incorporating the sequence data into searchable databases. The major step from a technical and an intellectual property perspective was the integration and automation of the whole set of processes into one turnkey method. The output of the process of automated DNA sequencing was not a "ladder" read on the gel, but a DNA sequence that could be fed into a DNA search engine to find new genes.

The development of HCS followed the same path as automated DNA sequencing. Cellomics, Inc. successfully integrated and automated multiple, previously single technologies including fluorescence microscopy; imaging science; fluorescence-based reagents (Taylor, 1992; Taylor *et al*., 2001); cell assays; and searchable databases. The result, HCS, formed a platform technology that was positioned to industrialize the field of cellomics.

2. Present applications

To date, a wide range of cellular processes have been explored with HCS. The first applications were measuring the activation of transcription factors (e.g., NF-kB) by quantifying the translocation from the cytoplasm into the nucleus (Ding *et al*., 1998) and quantifying the internalization of receptors into vesicles (Conway *et al*., 1999). Subsequently, screens for a wide range of transcription factors and receptors have been performed. An increasing number of cellular processes ranging from apoptosis, cell migration, cell cycle, G-protein coupled receptor activation (Walker *et al*., 1999), microtubule stability (Giuliano, 2003), and cytotoxicity (Abraham *et al*., 2004) have been implemented. It is believed that any cellular constituent including "biosensor" proteins and organelles can be specifically labeled and quantitative measurements can form the basis of an HCS screen (Giuliano and Taylor, 1998; Meyer and Teruel, 2003).

An ability to take more than one measurement from a cell has allowed the so-called multiplexing. For example, while the function (e.g., translocation) of the target protein in question can be monitored using one fluorescence channel (e.g., using green fluorescent protein tags (*see* Article 50, **Using photoactivatable GFPs to study protein dynamics and function**, Volume 5), or staining with antibodies coupled to fluoresein (*see* Article 58, **Immunofluorescent labeling and fluorescent dyes**, Volume 5)), other parameters of the cell can be simultaneously measured in another fluorescence channel, such as nuclear volume by staining with Hoechst dyes. This increases the information content of the assay.

3. Future developments

HCS has been accepted as an important approach to drug discovery by the pharmaceutical industry and it is now being incorporated into large-scale screens in academic research. The first generation platforms will now evolve as the market demands more from the platform. There will be advances in the individual component technologies that make up HCS, as well as in the integrated solutions. The optical and mechanical systems will become more sophisticated with the inclusion of modules for: reading microarrays of cells on chips; spectral deconvolution in order to analyze greater than four fluorescent reporters in the same assay; large area detection to increase the throughput; and additional fluorescence spectroscopic measurements to broaden the molecular information gained. Imaging science will be harnessed to perform faster and more powerful pattern recognition analyses that

will increase the robustness of the measurements. Training sets of data will allow the end user to better define the positive and negative attributes that the systems will be programmed to detect and to measure. In addition, the increased speed will permit the measurement of all possible morphometric and fluorescence parameters that will help define the optimal parameters for making decisions.

More specific, as well as multiplexed fluorescence-based reagents will be created; especially for live-cell screens. Multiplexing reagents with distinct spectral distributions, fluorescence lifetimes, and fluorescence anisotropy will be used in combination with reagents that can "modulate" cell constituent functions such as RNA-based reagents that can "knock down" coding and even noncoding genes (*see* Article 60, **siRNA approaches in cell biology**, Volume 5), as well as "chemical switches" that can regulate specific gene expression. Individual, as well as multiple cellular pathways will be interrogated with these advanced reagents opening up more complicated assays involving multiplexed measurements in four dimensions (x,y,z space and time). The creation of even more data per assay/screen (many terabytes) with these new tools will drive the development and implementation of more advanced informatics and cellular bioinformatics. The process of rapidly flowing through the production of data, the extraction of information and finally, the creation of knowledge will become faster and more powerful.

HCS promises to have the same impact on the field of cellomics, as automated DNA sequencing had on the field of genomics.

Short Specialist Review

Photobleaching (FRAP/FLIP) and dynamic imaging

George Banting
University of Bristol, Bristol, UK

1. Background

Fluorescence Recovery After Photobleaching (FRAP) and Fluorescence Loss In Photobleaching (FLIP) are related techniques, both of which are useful in the study of protein movement in live cells. Both techniques, particularly FRAP, have been used for many years to follow the diffusion of molecules (proteins and lipids) in the plane of the lipid bilayer of the plasma membrane (e.g., see Wey *et al*., 1981; Jacobson *et al*., 1976a,b; Axelrod *et al*., 1976; Edidin *et al*., 1976). Other related techniques are now also widely used (*see* Article 49, **Small molecule fluorescent probes for protein labeling and their application to cell-based imaging (including FlAsH etc.)**, Volume 5, Article 50, **Using photoactivatable GFPs to study protein dynamics and function**, Volume 5, Article 51, **FRET-based reporters for intracellular enzyme activity**, Volume 5, Article 55, **Imaging protein function using fluorescence lifetime imaging microscopy (FLIM)**, Volume 5 and Article 56, **Elucidating protein dynamics and function using fluorescence correlation spectroscopy (FCS)**, Volume 5, Article 57, **Quantum dots for multiparameter measurements**, Volume 5). Historically, specific cell-surface components were labeled with a fluorophore (e.g., fluorescein or tetramethylrhodamine) to enable them to be visualized during the imaging process. These early studies, pioneered by biophysicists, laid foundations upon which researchers from biophysicists to cell biologists now capitalize. The techniques of FRAP and FLIP became more accessible to cell biologists, particularly those with some molecular biological expertise, following the discovery of green fluorescent protein (GFP) and, more importantly, the isolation of the cDNA sequence that encodes it (Chalfie *et al*., 1994). GFP (including its spectral variants and related fluorescent proteins) is particularly attractive as a tool for studies in live cells since it is genetically encoded and emits visible light without any requirement for cofactors. Thus, over the past 10 years, many proteins have been tagged with GFP, expressed in cells, and then visualized by fluorescence microscopy. So, although the FRAP and FLIP techniques can, in theory, be applied to any fluorescently labeled molecule, this short review will assume that they are being used in the study of proteins that have been tagged with fluorescent proteins (FPs).

2. FRAP

Once a construct encoding a protein of interest tagged with GFP (or one of its spectral variants) has been generated and the recombinant protein has been successfully expressed in an appropriate cell (and shown to be correctly localized in that cell), it is possible to use FRAP and FLIP to study the movement of that protein. It is important to note that elevated expression of recombinant GFP-tagged proteins can lead to their mislocalization (e.g., see Girotti and Banting, 1996), so it is important that recombinant GFP-tagged proteins, as with any other epitope-tagged protein, are shown to be correctly localized before further studies are carried out. In the FRAP technique, a defined region of the cell (region of interest, ROI) being imaged is subjected to a short burst of high-intensity laser illumination. This treatment leads to photobleaching of the fluorophore (i.e., the FP) in the ROI. Recovery of fluorescence in the ROI can then be recorded by imaging the cell at regular intervals over a period of time (see Figure 1). This recovery of fluorescence is due to repopulation of the ROI by fluorescent molecules that have moved in from the surrounding area in exchange for photobleached molecules moving out. Thus, if we are considering a membrane protein, recovery of the fluorescent signal in the photobleached region can be considered to be an indicator of the diffusional mobility of that protein in the plane of the lipid bilayer. Indeed, this process can be followed quantitatively by time-lapse microscopy, with the fluorescent intensity of the ROI relative to that in the prebleach period (I/I_0) being plotted as a function of time (see Figure 2). This allows determination of the mobile and immobile fractions of the protein as well as the effective diffusion coefficient (D_{eff}) of the mobile fraction (Kubitscheck *et al*., 1994; Soumpasis, 1983; Axelrod *et al*., 1976), that is, how much of the protein is free to diffuse and how rapidly it does so if it can. Clearly, this technique is not only applicable to membrane proteins, but the

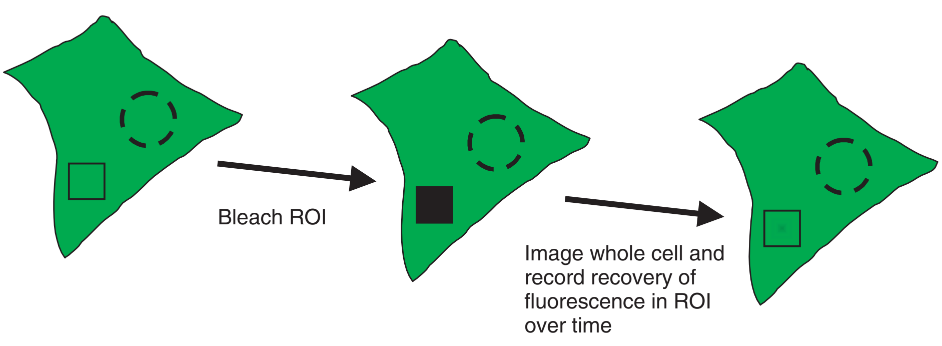

Figure 1 FRAP

- Image cell at low light intensity.
- Photobleach-defined area (ROI, boxed area above) using high light intensity.
- Image cell at low light intensity.
- Observe bleached area (black) adjacent to fluorescent area (green if using GFP-tagged protein).
- Observe repopulation of bleached area by fluorescently tagged protein.

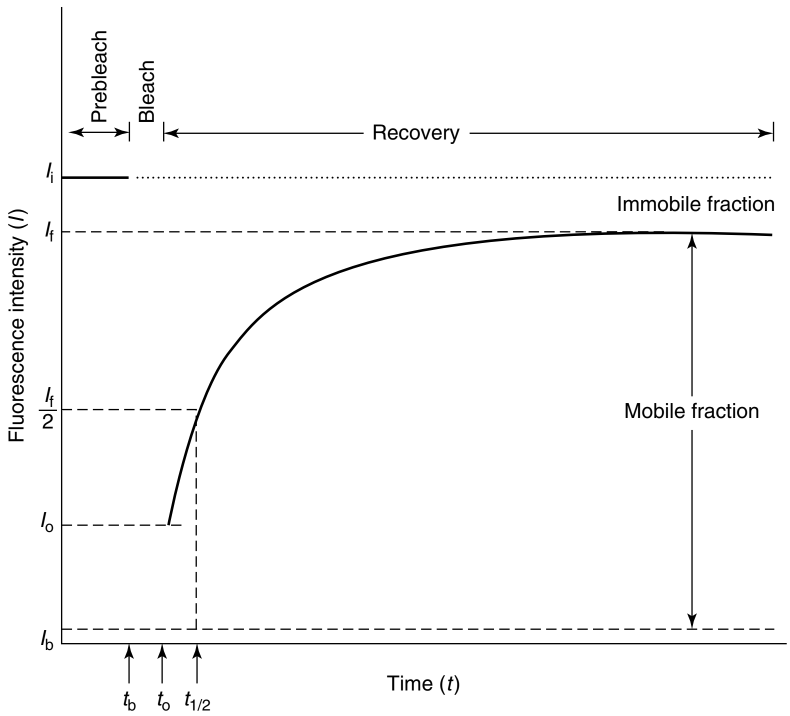

Figure 2 The region of interest (ROI) is photobleached between time t_b and t_0 and the fluorescence decreases from the initial fluorescence I_i to I_0. The fluorescence then recovers over time (due to replacement of bleached molecules by fluorescent ones) until recovery is complete (I_f). $t_{1/2}$ indicates the time taken for 50% recovery of the fluorescence signal. The intensity of the fluorescence signal in the ROI may well not return to the original value (I_i) following recovery (i.e., I_f does not equal I_i as shown above). This difference can be attributed to the immobile fraction of the fluorescently tagged protein

diffusion of soluble proteins in the cytosol can be assayed as can translocation of proteins (e.g., from cytosol to membrane or to nucleus) and protein exchange in macromolecular complexes (see Reits and Neefjes, 2001; Bastiaens and Pepperkok, 2000 for citations of examples).

3. FLIP

FLIP (see Figure 3) might be considered to be a corollary of FRAP. The difference between FRAP and FLIP is that whereas in FRAP the ROI is subjected to photobleaching only once, in FLIP it is repeatedly photobleached. The repeated bursts of photobleaching are interspersed with acquisition of images of the whole cell. This allows visualization of a gradual loss of fluorescence from the whole of the region that was originally fluorescent and occurs as fluorescent molecules move into the ROI, get photobleached, then move out again. Loss of fluorescence in different regions of the cell can be monitored over time, giving mobile and

immobile fractions in each of those regions as well as the D_{eff} for the mobile fraction. Clearly, this technique can also be used for both soluble and membrane proteins, and nicely complements FRAP.

4. Caveats

There are caveats that must be borne in mind when interpreting FRAP and FLIP data. For example, the use of FRAP to study protein diffusion in the lipid bilayer of the plasma membrane is relatively straightforward since the proteins being followed are present in a continuous two-dimensional membrane system. However, many intracellular membrane systems are highly dynamic and not necessarily continuous; therefore, fluorescence recovery in a ROI will be due to a combination of diffusion in the plane of the lipid bilayer, reconfiguration of the membrane system, and the degree of continuity/discontinuity of that membrane system. A further point that must be borne in mind when using FRAP (or FLIP) is that reversible photobleaching of GFP can occur (Swaminathan *et al*., 1997). As described elsewhere (Bastiaens and Pepperkok, 2000), a simple way to determine whether reversible photobleaching is occurring or not is to change the size of the ROI that is photobleached. The kinetics of recovery will be unaffected by the size of the ROI if recovery is due to reversible photobleaching. The effect of de novo protein synthesis on FRAP and FLIP results should also be considered, that is, is

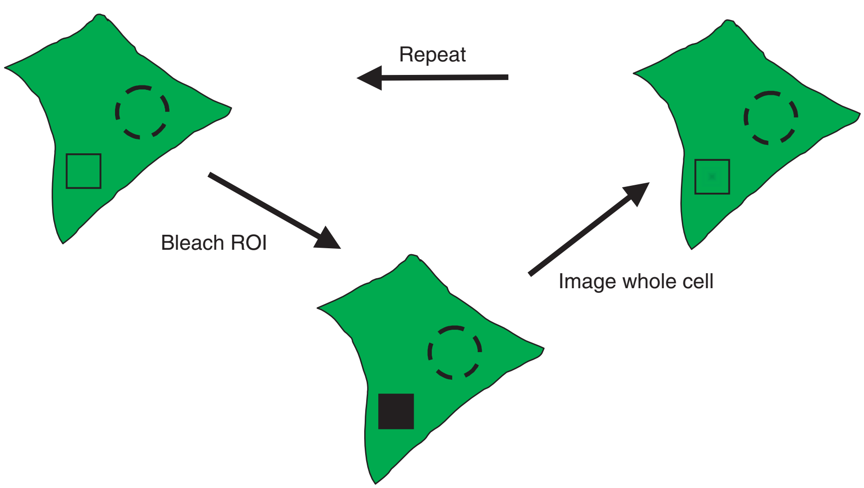

Figure 3 FLIP

- Image cell at low light intensity.
- Photobleach defined area (ROI, boxed area above) using high light intensity.
- Image cell at low light intensity.
- Repeat above two steps multiple times.
- Observe gradual loss of fluorescence throughout entire cell.

recovery of fluorescence in an ROI due to movement of an already synthesized protein from another location to the ROI or is it due to repopulation of the ROI by newly synthesized material? This question can be addressed by performing the FRAP and FLIP analysis on cells that are incubated in the presence of a protein synthesis inhibitor such as cycloheximide.

Short Specialist Review

Probing protein function in cells using CALI

Thomas J. Diefenbach and Daniel G. Jay
Tufts University School of Medicine, Boston, MA, USA

1. Introduction

Proteomics is advancing beyond the cataloging of the complement of expressed proteins in cells. Understanding protein function within the context of the cell is a key final step in proteomics. Traditionally, molecular genetics has been used to test protein function through knockout and overexpression of relevant genes. Chromophore-assisted laser inactivation (CALI) provides a direct means for acute inactivation of *in situ* protein function.

2. The process of CALI

Nonfunction-blocking antibodies (IgG, IgM, Fab fragments, single chain antibodies or scFvs) are covalently linked to a photosensitizer dye such as malachite green isothiocyanate (MG-ITC; Figure 1).

The labeled antibodies are loaded into cells using electroporation, trituration-loading, scrape-loading, and microinjection, or are simply applied to the surface of the cells or preparation to address surface proteins (Buchstaller and Jay, 2000). The preparation is then exposed to a specific wavelength of light. The light is absorbed by the dye and this energy raises the chromophore into an excited state. Upon relaxation of the excited dye, free radicals are generated and the cycle repeats (Figure 2). In the case of CALI utilizing malachite green, it is thought that energy is transferred to a water molecule, and a hydroxyl radical is formed with a lifetime of 1 ns and a half maximal radius of inactivation of 15 Å (Jay, 1988; Liao *et al*., 1994; Linden *et al*., 1992).

An illustration of the spatial specificity of the radius of action of CALI comes from a study of the three 25-kDa subunits of the T-cell receptor complex (Liao *et al*., 1995). CALI targets either of the subunits bound by the antibody, with a slight effect on the antibody binding to the neighboring subunit, and no other effects on other components of the receptor complex.

The hydroxyl radical can damage the protein in different ways through reactions with different amino acid side chains (arginine, histidine, methionine, phenylalanine, tyrosine, tryptophan) (Halliwell and Gutteridge, 1989). A fluorophore-based

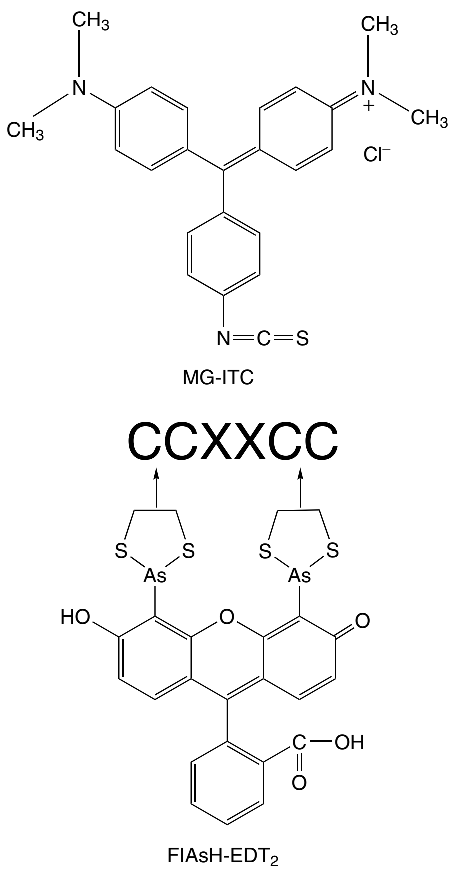

Figure 1 Atomic structures of two common CALI photoactivators, malachite green isothiocyante (MG-ITC), and fluorescein isothiocyanate (FITC), are covalently linked to free amines (lysine) on the antibodies or scFv fragments through reaction of the isothiocyanate (N=C=S) with amine to form a thiourea. Also shown are two membrane-permeable fluorophores, ReAsH-EDT$_2$ and FlAsH-EDT$_2$, each with two arsenics that bind a tetracysteine motif (X is any amino acid except cysteine) expressed as part of the recombinant target protein of interest

derivative of CALI utilizing fluorescein isothiocyanate (FITC; Figure 1) instead of malachite green has also been developed and is referred to as FALI (Fluorophore-assisted light inactivation; Beck *et al*., 2002). The reactive species for FALI is singlet oxygen, and experiments with free-radical quenchers suggest a larger half-maximal inactivation radius of ~40 Å (Beck *et al*., 2002). Singlet oxygen has a much greater lifetime in cells of 200 ns versus 1 ns for the hydroxyl radical. Although the singlet oxygen likely reacts with four amino acids (tryptophan, histidine, methionine, and cysteine), the reactions are complex, can proceed through several mechanisms yielding distinct decomposition products (Halliwell and Gutteridge, 1989), and are as much as 300-fold slower than the reaction of the hydroxyl radical with similar amino acids. The lifetimes of free radicals are limited by endogenous free-radical scavengers (ascorbate and glutathione for hydroxyl

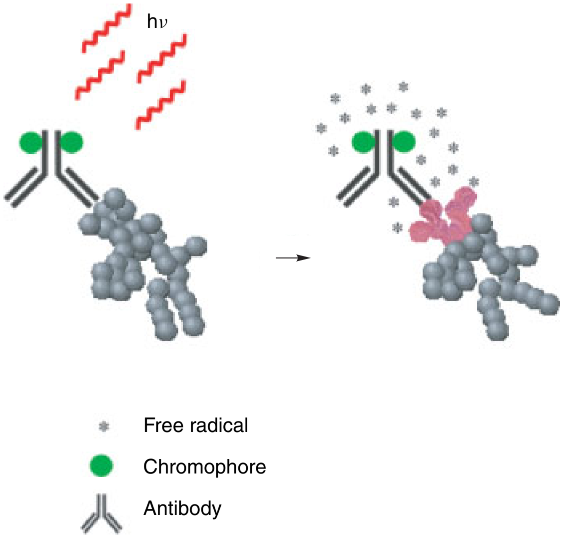

Figure 2 Schematic of the CALI process. The dye-labeled antibody binds the target protein and is irradiated with either laser or incandescent light (hν). Energy is transferred from the dye to water or free oxygen to form hydroxyl radical or singlet oxygen, respectively. These short-lived reactive species (*) cause local and irreversible damage to specific amino acids on the bound protein. This damage is spatially restricted, and may have many consequences, including perturbation of protein conformation, enzymatic activity, or protein–protein interactions

radicals, ergothioneine, and carotenoids for singlet oxygen; Chaudiere and Ferrari-Iliou, 1999). The cell's growth state may also affect its ability to deal with oxidative damage by free radicals, as proliferating or tumorigenic cells display an inherently greater capacity to deal with oxidative stress (for review see Das, 2002). These factors should be considered when assessing the applicability of different CALI methods.

CALI is performed on one of three scales: micro-CALI, macro-CALI, and FALI. Macro-CALI employs a large laser to produce a 2–5-mm diameter laser spot useful for irradiation of tissue samples, culture dishes, or microtiter wells. Micro-CALI uses a less powerful laser, the light of which is directed through the optics of an inverted microscope, yielding spot sizes of 5–100 μm in diameter. Micro-CALI can therefore be used to target protein populations in individual cells or within specific cellular compartments. FALI employs diffuse light, allowing many samples to be treated in parallel in multiwell plates.

Genetic compensation is not as much a concern with the acute loss of function afforded by CALI as it can be for RNAi and genetic loss of function. Furthermore, the RNAi approach cannot distinguish between different proteins arising through posttranslational modification, while CALI may distinguish between isoforms with isoform-specific antibodies. Unlike RNAi, CALI can be performed any time after antibody application or loading, and recovery of protein function will depend on turnover of the target protein. CALI is thus ideally suited to address protein function in the dynamic and rapidly changing cellular environment. Limitations of CALI

include: the requirement for a specific antibody, a need to load antibodies into cells for intracellular targets, and recovery will occur with *de novo* protein synthesis.

3. Developments in CALI technology

CALI technology has been aided by expanding the selection of photoactivatable dyes, or by changing the way in which those dyes bind to the target protein. FALI utilizes fluorescein, which is excited by higher energy, shorter wavelength light, permitting the use of conventional light sources, and the ability to illuminate entire multiwell plates for high-throughput, cell-based proteomic screens (Beck *et al*., 2002; Eustace *et al*., 2002). These screens have addressed cell surface targets by adding exogenous antibody to the cell preparations prior to FALI. One of the advantages of FALI as a screening tool is that it can take advantage of single chain antibody (scFv) libraries to bypass the traditional high-throughput bottlenecks in a "top–down" approach to screen protein function directly, as a complement to extensive mutational analyses. As part of such a proteomic approach, FALI identifies scFvs that are then used to identify their targets immunoprecipitation and mass spectrometry.

One molecular genetic approach to CALI employs the use of green fluorescent protein (GFP) as a genetically encoded photoactivator (Rajfur *et al*., 2002; *see also* Article 48, **Probing cellular function with bioluminescence imaging**, Volume 5 and Article 50, **Using photoactivatable GFPs to study protein dynamics and function**, Volume 5). GFP is relatively inefficient as a photoconverter likely on account of shielding of the fluorophore nested within its barrel structure, and may thus require longer illumination periods for full effect (Surrey *et al*., 1998). Two new methods for genetically targeted CALI have been developed, using genetically encoded protein tags to which a biarsenyl fluorophores selectively bind (*see* Article 49, **Small molecule fluorescent probes for protein labeling and their application to cell-based imaging (including FlAsH etc.)**, Volume 5). FlAsH-FALI (FlAsH, or fluorescein derivative with two As(III) substituents on the 4′ and 5′ positions) utilizes site-specific fluorescent labeling of recombinant proteins by genetically tagging the target protein with a tetracysteine motif. This motif is then recognized by a membrane-permeant, biarsenical fluorescein derivative (Figure 1). This labeling method was initially tested in cells by fusing the tetracysteine motif to the COOH-terminus of a mutant of cyan fluorescent protein (ECFP) (Griffin *et al*., 1998). FlAsH only fluoresces upon binding to the cysteine motif on the protein of interest (Adams *et al*., 2002), although nonspecific binding to endogenous tetracysteine motifs is a potential concern. FlAsH-FALI effects will be limited to expressed proteins, with endogenous proteins not affected except perhaps through collateral damage. Uniform penetration of the fluorescein derivative into tissue and residual background fluorescence through nonspecific binding are issues to be considered for FlAsH-FALI, depending on the system. FlAsH-FALI also requires the coaddition of 1,2-dithiols to outcompete FlAsH binding to endogenous cysteine pairs (Adams *et al*., 2002). Since FlAsH-FALI uses fluorescein, which requires higher energy, shorter wavelength light (typically 480–490 nm) that is

absorbed by cells, a membrane-permeant, red biarsenical fluorophore (ReAsH-EDT_2; Figure 1) was developed, which is excited by longer wavelength, 593-nm light (ReAsH-CALI; Tour *et al*., 2003). With ReAsH-CALI, maximal inactivation of connexin-43, a component of gap junctions, was achieved using a 150-W xenon arc lamp with only 10 to 30 s of irradiation (Tour *et al*., 2003). Combined, these approaches expand the utility of CALI and create a bridge for CALI as an adjunct to molecular genetic approaches.

4. Applications of CALI at the cellular level

CALI has been used to examine the roles of proteins that are members of larger protein families and that have not yet been engineered transgenically or lack specific pharmacological blockers. For example, the myosin superfamily of actin-based molecular motors comprises 18 classes. Genetic knockouts of individual myosins are problematic since a single cell possesses members from many myosin classes and often more than one isoform. CALI has been used to probe the function of distinct myosins: myosins 1c and Va (Wang *et al*., 1996), and myosins IIA and IIB (Diefenbach *et al*., 2002) in relation to the motility of the growing tips of nerve cell processes (for earlier review, see Buchstaller and Jay, 2000). CALI technology has also been applied to the family of neural cell adhesion molecules (NCAMs). Neurons from knockout mice that do not express the cell adhesion molecule, L1, fail to extend neurites on an L1 substrate (Dahme *et al*., 1997). In this case, the complete lack of the appropriate adhesion molecule precluded study of its role in cell shape change because the cells failed to initiate extension of their neuritic processes. Micro-CALI of L1 resulted in neurite retraction without affecting the protrusive activity of the neurite tips, while micro-CALI of NCAM-180 impaired protrusive activity at the tips of extending neurites without affecting neurite extension (Takei *et al*., 1999).

CALI has also been applied to examination of proteins implicated in cancer cell growth and migration, including the actin-associated protein ezrin (Lamb *et al*., 1997), and the protein tyrosine kinase, pp60 c-src (Hoffman-Kim *et al*., 2002). In pp60 c-src knockout mice, no major neurological deficits were found (Soriano *et al*., 1991). Yet, with acute inactivation of pp60 c-src, extension of neuronal processes in culture was dramatically increased, implicating this tyrosine kinase as a negative regulator of laminin-mediated neuronal growth. The molecular chaperone, heat shock protein 90α (hsp90α) was recently identified in a FALI-based, high-throughput proteomic screen, and found to facilitate, via an extracellular route, cancer cell migration through its interaction with matrix metalloproteases (Eustace *et al*., 2004). CALI also has potential in the field of prion protein research (Graner *et al*., 2000). These studies underscore the utility of CALI in dissecting the cellular roles of individual members of large protein families.

5. Applications of CALI in vivo

CALI can also address protein function at distinct developmental timepoints in vivo or during dynamic processes such as cell division and cell migration. CALI

of fasciclin I reduced bundling of pioneer axons in the developing grasshopper (Jay and Keshishian, 1990; Diamond *et al*., 1993), and CALI of patched protein altered cell fate in *Drosophila* (Schmucker *et al*., 1994). CALI of the repulsive guidance cue ephrin-A5 in chick optic tectum in vivo limits growth of axons of the retinotectal projection (Sakurai *et al*., 2002). In organ culture of retina and optic nerve, CALI of myelin-associated glycoprotein resulted in regeneration of retinal ganglion cells after an optic nerve crush (Wong *et al*., 2003). Thus, CALI technology has proven itself in many in vivo applications.

To conclude, CALI technology provides a direct means of assaying protein function and dynamics in cells and tissues with great temporal and spatial precision. It can serve as a complementary approach to knockout, RNAi, antisense, pharmacological or other approaches in that it provides a means of addressing the endpoint of a proteomic strategy – how the function of the protein directly impacts cellular function.

Short Specialist Review

Imaging protein function using fluorescence lifetime imaging microscopy (FLIM)

Yan Gu and Daniel Zicha

Cancer Research UK London Research Institute, London, UK

1. Introduction to FLIM techniques

Fluorescence lifetime is the average time for molecules to spend in the excited state before returning to the ground state with either emitting a photon or transferring their energy nonradiatively to surrounding molecules. Lifetimes of most molecules are measured in nanoseconds and are influenced by local environment such as collisional quenching, pH variation, temperature, and Fluorescence Resonance Energy Transfer (FRET). Lifetime gives valuable insight into the binding of emitting molecules, and surrounding chemical and physical parameters.

Lifetime is usually measured by FLIM (fluorescence lifetime imaging microscopy), which can be broadly divided into frequency-domain approaches and time-domain approaches. Frequency-domain FLIM modulates the emission of fluorophores with sinusoidal excitation, and uses the modulation difference and phase delay between excitation and emission to calculate their lifetime (Lakowicz, 1999). Time-domain FLIM relies on fast-gated detection of individual photons emitted by fluorophores excited by a femtosecond laser pulse in order to "snap" their decay, from which their lifetime is processed. Time-domain approaches are implemented as either wide-field or point-scan FLIM. Wide-field FLIM uses a fast-gated optical intensifier and a CCD camera to acquire a time sequence of 2D decays with high-resolution time delay (Cole *et al*., 2000). Point-scan FLIM, on the other hand, relies on 2D scan to acquire spatial information. Recent improvements in the Time Correlated Single Photon Counting (TCSPC) technique have greatly facilitated FLIM measurements (Becker *et al*., 2003).

Other specialized FLIM techniques include anisotropy FLIM (rFLIM), spectral FLIM (sFLIM), and endoscopic FLIM (Becker *et al*., 2002; Hanley *et al*., 2002; Siegel *et al*., 2001). rFLIM uses perpendicularly polarized decay kinetics to explore the multiplicity of rotational correlated depolarization or anisotropy, reflecting heterogeneity in molecular populations and the size, shape, and internal motion of a complex (Clayton *et al*., 2002). sFLIM measures lifetime in a number of spectral bands and extends FLIM further into spectral dimension. In biological multicomponent systems, sFLIM provides better assessment to the lifetime

distribution of single fluorescent species, and increases contrast to distinguish multiple fluorophores or heterogeneity of local environment. Endoscopic FLIM combines FLIM with endoscopes, making possible in vivo lifetime measurements in tissue without staining (Tadrous *et al*., 2003).

Sensitivity is critical in lifetime measurements, especially when the molecular concentrations are low or interactions are weak. In many protein-interaction experiments, relative measurements such as lifetime ratio of different proteins or one protein over different time points are preferred to increase the sensitivity. A sensitive approach, referred as the *acceptor photobleaching FLIM*-FRET, was adopted from intensity FRET (Chen *et al*., 2003). Using this approach, the binding proteins can be solely identified by the lifetime difference of the donor before and after photobleaching. One of the important issues of this method is the oxygen-related radicals generated during photobleaching. Because they have very short lifetime, their presence would decrease the average lifetime of donors. Lampert *et al*. (1983) suggested removing the oxygen before the experiment to avoid these radicals and the related acceptor recovery after photobleaching.

Recent research has started to focus on live-cell FLIM approaches (Ng *et al*., 1999; Krishnan *et al*., 2003; Grecco *et al*., 2004; Errington *et al*., 2005; Treanor *et al*., 2005). FLIM on fixed cells provides a snapshot of protein interactions, whereas live-cell FLIM can reveal their dynamics. Live-cell FLIM can also avoid the artifacts caused by the fixation. The difficulties of live-cell FLIM, however, are associated with the fact that live cells are quite vulnerable to phototoxicity and photobleaching. Excitation strength must be controlled to acceptable levels. Therefore, FLIM measurements usually suffer from low signal-to-noise ratio and long acquisition time. A typical FLIM measurement takes several minutes, which makes it difficult to attain high temporal resolution. Faster FLIM approaches are often achieved with compromises in spatial resolution, spatial field of view, or detection accuracy. Increasing FLIM detection sensitivity seems to be the key issue to the live-cell FLIM. The influence of experimental conditions on the lifetime is another issue that has not been explored thoroughly. For instance, the local environment in fixed cell is stable, in contrast to a dynamic process in the living cell. Molecular diffusions in living cells provide rather different environment from that of fixed cells, and would in turn change the heterogeneity of lifetime.

2. FLIM data processing

Data processing is an important part of FLIM. As emission is a random process, each excited molecule has the same probability of emitting in a given time period. Statistically, the time-dependent fluorescence $I(t)$ reflects an exponential decay of the excited-state populations as (Lakowicz, 1999)

$$I(t) = \sum_{i=1}^{m} I_i(0)\mathrm{e}^{\frac{t}{\tau_i}} \tag{1}$$

where and $I_i(0)$ and τ_i are the emission (at t = 0) and the lifetime of ith fluorophore population, and m is the number of fluorophore populations in the system. In time-domain FLIM, original data are arranged in such a way that at each pixel, there

is a time sequence of intensities following the decay kinetics of molecules. The nonlinear least-squares fitting proposed by Grinvald and Steinberg (1974) is still widely used (Lakowicz, 1999). In a mono-exponential system, such a fit usually produces accurate estimation of the average lifetime. However, in multiexponential systems such as most biological systems, this algorithm can sometimes generate ambiguity, that is, more than one set of results will satisfy equation (1). Such a problem inherently originates from the fact that parameters $I_i(0)$ and τ_i are correlated, and one can either vary the lifetime to compensate the amplitude, or vice versa (Grinvald and Steinberg, 1974). In a typical protein–protein interaction system, at least two lifetimes (free and FRET-involved donors) need to be identified. Higher dimensions are required if spectral cross talk from acceptor and autofluorescence need to be considered. Fitting more than two components is very difficult and insensitive without many data points and auxiliary information (Cubeddu *et al*., 2002). In some cases, estimations between biexponential fit and triexponential fit to a true system are not quite distinguishable from Goodness of Fit (χ^2_R). Practical measures to avoid the ambiguity include (1) setting up lifetime boundaries using additional system knowledge, (2) obtaining images with high signal-to-noise ratio, (3) sampling as many data points as possible, and (4) acquiring additional information with auxiliary experiment to reduce the number of variables or set up additional restraints to the correlation between $I_i(0)$ and τ_i.

Various postprocessing algorithms have been developed to improve the signal-to-noise ratio and lifetime accuracy. Global analysis algorithm proposed by Verveer and Bastiaens (2003) assumes that neighboring pixels have similar lifetime, and different pixels in an image can be treated as independent measurements. They applied the algorithm in frequency-domain FLIM to study multiexponential systems with a single modulation frequency. Similar strategy is used in time-domain FLIM to increase the signal-to-noise ratio. Such an algorithm works well when images have good signal-to-noise ratio, and reducing spatial resolution is not an issue. Another option to improve the data quality without increasing data points is to optimize the sampling arrangement. Usually, data are sampled with equal time period. The fit process takes these points with equal weight. Apparently, variations of the decay signal influence the lifetime estimation differently. For instance, time points before 2τ have higher signal-to-noise ratio and therefore are more accurate than those after 3τ. It is helpful to arrange the sampling nonlinearly and emphasize more on the data with higher quality in the fit algorithm.

In this paper, we propose an approach using intensity-based spectral unmixing to provide auxiliary information to lifetime measurements. Spectral unmixing is a well-established image processing methodology, which is based on the approximation that the spectral signature of a test sample is the sum of a linear combination of abundance weighted spectra of constituent pure classes (Petrou and Foschi, 1999). Using the emission spectra of specified pure fluorochromes as a reference, the fluorescence of the corresponding fluorochrome within a complex can therefore be precisely determined from its composite spectrum. In a double-fluorophore system, the linear unmixing algorithm can be expressed as

$$F_m(x, y, \lambda) = C_1(x, y)F_1(\lambda) + C_2(x, y)F_2(\lambda) \qquad (2)$$

where $C_1(x, y)$ and $C_2(x, y)$ are unknown abundance factors of the two fluorochromes at pixel location (x, y), whose spectral responses are expressed as $F_1(\lambda)$ and $F_2(\lambda)$ respectively, and $F_m(x, y, \lambda)$ is the spectral response of a test sample. $F_1(\lambda)$ and $F_2(\lambda)$ are measured using single fluorochrome specimens (controls). To avoid interference from environment, controls and the test sample are made from the same specimen, and are imaged under exactly the same conditions whose influence is cancelled out during the unmixing process.

Assuming lifetime is detected within wavelength λ_1 and λ_2, the steady state emission ratio can be given as (Lakowicz, 1999)

$$\frac{I_1(0)\tau_1}{I_2(0)\tau_2} = \frac{C_1(x, y)\displaystyle\int_{\lambda_1}^{\lambda_2} F_1(\lambda)\,\mathrm{d}\lambda}{C_2(x, y)\displaystyle\int_{\lambda_1}^{\lambda_2} F_2(\lambda)\,\mathrm{d}\lambda} \tag{3}$$

Equation (3) provides an extra restraint to equation (1), which not only helps to solve the ambiguity problem but also improves the lifetime accuracy. If m fluorophores are in the complex, equation (3) consists of $m - 1$ ratios.

Nowadays, with the increasing demand of high spatial/temporal resolutions, more and more protein lifetime measurements are based on the combination of confocal microscopes, multiphoton excitation, and TCSPC (Becker & Hickl). Laser scanning confocal microscope LSM 510 META (Carl Zeiss Ltd.) allows multispectral images to be collected simultaneously without compromising resolution and efficiency. The 32 spectral detectors are aligned in such a way that they can cover any emission wavelength between 378.4 and 720.8 nm, with a maximum resolution of 11 nm. Outputs from a maximum of eight channels can provide continuous hyperspectral coverage of a sample's emission. Using spectral unmixing, we have successfully separated ECFP from EGFP and EYFP from EGFP. On the basis of LSM 510 META, we are exploring the possibility to associate FLIM with spectral-based measurements in a single cell mount, which provides multidimensional information (spatial, temporal, spectrum, and lifetime) for protein colocalization and interaction. Such combinations do not significantly increase the experimental load, as lifetime measurements and spectral emission can be accomplished in a single sample mounting. Since spectral measurements are much quicker than lifetime, and the additional steady state information helps to reduce data sampling in FLIM, it might speed up data acquisition. A macro program can be implemented to automatically conduct both measurements.

3. Protein functional interpretation using FLIM

Association with local environment makes lifetime a very powerful indicator to explore protein's neighborhood. However, it also makes the comparative measurement in a cell population very difficult. A fluorophore may have different lifetimes in different environments. For instance, ECFP has an average lifetime of 2.6 ns when fused with C/EBPα proteins expressed in GHFT1-5 cell nuclei (Chen

et al., 2003). This lifetime is shortened to 2.3 ns when transfected into HEK cells, and even becomes shorter (phase lifetime: 1.32 ns and modulation lifetime: 2.23 ns) when fused with nuclear bipartite nucleoplasmin in live Vero cells (Becker *et al*., 2004; Pepperkok *et al*., 1999). In FLIM-FRET, the variation of a donor's lifetime in a test sample from that of a donor-only control is an indicator of the energy transfer. Even if both samples are prepared under the same conditions and cells express at the same level, local heterogeneity between two independent cells will generate lifetime difference, regardless of the existence of FRET. Furthermore, since the resultant interaction distance is usually a statistical average, the quantified lifetime is often used only to deduce qualitative conclusions, such as reduced lifetime of donors which indicates the binding of proteins, while increased lifetime implies the opening of protein complexes (Ng *et al*., 2001).

According to literature, FLIM has been applied to a range of protein function studies, such as contrast enhancement of protein environment, and colocalization and interaction between proteins. Image contrast enhancement by lifetime can be used to distinguish molecules in different local environment, which may not be resolvable from their emission spectra. For example, collagens are abundant proteins in human tissue. Experimental data suggest that their autofluorescence is at least partly due to cross-linkage formed by the action of lysyl oxidase on lysine and hydroxylysine side chain polymer (Eyre, 1987). Such cross-linkages vary with tissue type and local environment such as glucose concentration, and increase with tissue age (Pongor *et al*., 1984). These variations alter the local lifetime and can provide contrast to distinguish collagens with different ages. As collagens emit naturally, FLIM has the potential to enhance the contrast of in vivo tissue imaging. Tadrous *et al*. (2003) used lifetime for histopathological assessment of breast cancer tissues.

Protein colocalization is another widely used lifetime application. Traditionally, colocalization refers to the pixel registration of different lifetime images. Owing to the diffraction limitation of optics, such a protein copresence is restricted to about 200 nm in resolution, which is quite coarse in protein's scale (several nanometers). The development of FLIM-FRET techniques greatly increases the resolution (Bacskai *et al*., 2003; Chen and Periasamy, 2004). When two different proteins or different parts of a protein are tagged with different fluorophores, FRET signal will report colocalizations or binding activities if the proximity of two fluorophores is less than 10 nm. Bacskai *et al*. (2003) applied double immunofluorescence to the brain tissue Tg2576 transgenic mice, which overexpress mutant human amyloid precursor protein, leading to the progressive formation of senile plaques similar to those found in Alzheimer's disease. FITC-10 d5 and rhodamine-labeled 3 d6 antibodies were used to recognize epitopes specifically bound to the N-terminal of amyloid-β (amino acids 3 to 6 and 1 to 5 respectively). The lifetime distributions revealed that they are colocalized on amyloid-β deposits within 10 nm, and two epitopes have different relative conformations. Apparently, protein colocalization by FRET only is limited within 10 nm. While pixel-based colocalization provides wider field of view and FRET-based colocalization gives high resolution, the combination of both techniques provides a high dynamical range and nanometer resolution solution to identify the formation of protein complexes.

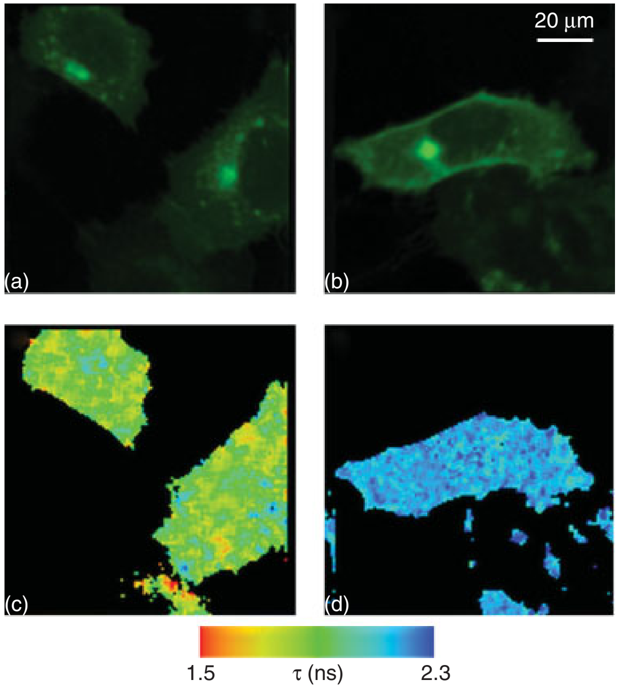

Figure 1 N-WASP/Cdc42 interaction in fixed NIH 3T3 fibroblasts. Images, acquired using a multiphoton TCSPC system, represent donor fluorescence intensity (a and b) and associated lifetime maps (c and d) for cells expressing EGFP-N-WASP & Myc-Cdc42, either in the presence (a and c) or absence (b and d) of Cy3-MycAntibody acceptor labeling. Lifetime images are presented in pseudocolor, defined by the associated scale

Typical interaction applications include quantitative ion concentration and calcium-binding studies, the pH fluctuations, and oxygen concentration change monitoring in cells (Bastiaens and Squire, 1999; Periasamy *et al*., 2001). In our studies of the mechanisms of cell motility, we found that inhibition of Cdc42 or N-WASP in NIH 3T3 fibroblasts led to 30% reduction of cell speed. This significant reduction can be explained by the fact that two molecules act together in a complex. In order to directly address this hypothesis, we used FLIM-FRET to visualize the interaction between Cdc42 and N-WASP (Figure 1), in collaboration with T. Ng, Randall Centre, King's College London, UK, and B. Vojnovic, Gray Cancer Institute, Northwood, UK (Monypenny, 2003). As shown in Figure 1, the shortening of lifetime of EGFP-N-WASP demonstrates the occurrence of FRET and therefore a direct indication of N-WASP and Cdc42 being in a very close proximity (Figure 1c in comparison to Figure 1d).

When protein–protein interaction lasts for a relatively long time period (compared with the measuring speed of FLIM), live-cell FLIM can be used to monitor its dynamics. Peter *et al*. (2004) applied live-cell FLIM to study the receptor-kinase interaction between the chemokine receptor (CXCR4) and protein kinase Cα (PKCα) in carcinoma cells. They found the CXCR4-PKCα complex forms concomitant with the endocytosis process, which would be difficult to detect in fixed

cells. With dynamic FLIM-FRET, Martin-Fernandez *et al*. (2004) observed a progressive decrease in FRET efficiency during the capsid disassembly for adenovirus serotype 5 (Ad5) in living CHO-CAR cells. On the basis of FRET efficiency, they concluded that the disassembly process has two sequential protein dissociation rates.

In conclusion, developments in confocal microscopy enable the spectral- and lifetime-based techniques to be combined in the lifetime measurement, providing more sensitive and accurate estimations. With the advance of technology, FLIM is being driven toward quantitative protein functional interpretations in live cells for both in vitro and in vivo applications.

Elucidating protein dynamics and function using fluorescence correlation spectroscopy (FCS)

Petra Schwille
Dresden University of Technology, Dresden, Germany

Fluorescence correlation spectroscopy (FCS) was first described as a very sensitive relaxation technique by Magde *et al*. (1972) and during the following years has been applied by several groups to determine the concentration and mobility (in particular, diffusion) parameters as well as chemical kinetics. In contrast to classical fluorescence spectroscopy that measures the average signal, FCS resolves temporal variations in fluorescence, induced by statistical fluctuations of measurement parameters such as particle number and brightness. Consequently, all dynamic processes that change particle brightness, mobility, and concentration can be sensitively analyzed in any transparent medium.

The ability of FCS to measure local fluorophore concentrations and diffusion coefficients with minimal interference with the biological system has had important consequences for applying FCS to cell-based problems. However, it was not until the early 1990s when FCS was combined with a confocal microscopy setup that this promise was realized. The small volume resolution of FCS achieved using confocal imaging (down to the femtoliter range, which is of the order of the volume of an *E. coli* cell), has provided a real breakthrough in the FCS field. The problem of low signal-to-noise levels that had so far substantially limited its applications and frustrated many researchers, who were originally convinced by the conceptual beauty of the technique, was now overcome. Rigler and coworkers, who were the first to apply FCS in confocal setups, reported signal-to-noise levels up to 1000 and could easily resolve the transits of single fluorescent molecules through the illuminated focal measurement volume (Rigler *et al*., 1993; Eigen and Rigler, 1994).

It is fair to say, therefore, that the confocal FCS scheme introduced by Rigler *et al*. triggered a true renaissance of this technique. Biochemists, molecular and cell biologists then immediately recognized the potential of FCS for ultrasensitive analysis of biomolecular dynamics in homogeneous assays. Today's standard FCS applications range from the determination of concentrations and mobility parameters, rate constants of association and dissociation reactions, or enzymatic turnovers, to timescales of internal fluctuations due to structural or photophysical dynamics. In combination with specific dyes, internal fluctuation patterns can yield

environmental parameters such as pH, ionic strength, or oxygen levels. A review of solution-based applications is provided by Elson and Rigler (2001). In all these applications, the essential information can be drawn from the observation of single molecules entering and leaving a laser-illuminated confocal volume element by random diffusive motion, one by one, inducing characteristic fluctuations in the fluorescence signal. Molecular residence times in the observation volume gives direct access to mobility parameters. Fluctuation strength, on the other hand, is inversely related to the occupation number and, thus, the concentration. Internal dynamics can usually be resolved if the processes to be investigated (e.g., conformational changes) change the fluorescence properties of the fluorophore. The characteristic fluctuation pattern is then not only induced by the entering and leaving of the measurement volume but also by reversible on–off blinking of the fluorophore during the dynamic process to be investigated.

A key application of FCS in cell-based assays is in determination of protein–protein interactions, be it of receptor–ligand binding on cell membranes or other recognition processes. However, enzymatic turnovers in the living cell can also be monitored. Standard FCS is rather limited in following molecular interactions, because its key measurement parameters, the residence time of single molecules in the confocal spot or the local concentration, are rarely affected by specific reactions in a predictable and reliable way. Sufficient measurement selectivity can only be guaranteed if the interaction partners are labeled with distinct fluorescent probes, like in other fluorescence microscopy applications such as colocalization or FRET assays. However, in contrast to these imaging-based techniques, dual-color FCS does not depend on the spatial proximity of two labels that could or could not reflect true mutual protein binding. Rather, the so-called dual-color cross-correlation technique probes the concomitant *movement* of particles by quantifying the number of coincident fluctuation events in two independent measurement channels (see Figure 1). Noninteracting, single-labeled molecules induce only noncoordinated fluctuations in either one of the detection channels (here, green or red). Only true interactions between two differently labeled molecules make them codiffuse in a way that induces coincident fluorescence fluctuations in both measurement channels every time a complex molecule makes a transit (Schwille *et al*., 1997). Assuming the dual-color confocal setup is well calibrated, the amplitude of the so-called cross-correlation function is directly proportional to the relative number of bound species. This means that molecular interactions can be comfortably determined in situ, even in the complex cellular environment.

Despite the huge promise of dual-color cross-correlation as a proteomic technique, few intracellular applications have so far been reported, although commercial FCS systems are available. One potential reason for this surrounds the high sensitivity of the method, making it susceptible to several artifacts, including the confounding effects of nonspecific binding of the labeled molecules to cellular structures, or photobleaching of the probes. Furthermore, concentrations of fluorescent molecules above 100 nM seriously lower the signal-to-noise ratio and, thus, sensitivity.

A major technical challenge is guaranteeing the stable overlap of the green and the red excitation volumes in two-color applications. However, it has been found that two-photon excitation, a nonlinear excitation mode frequently employed in

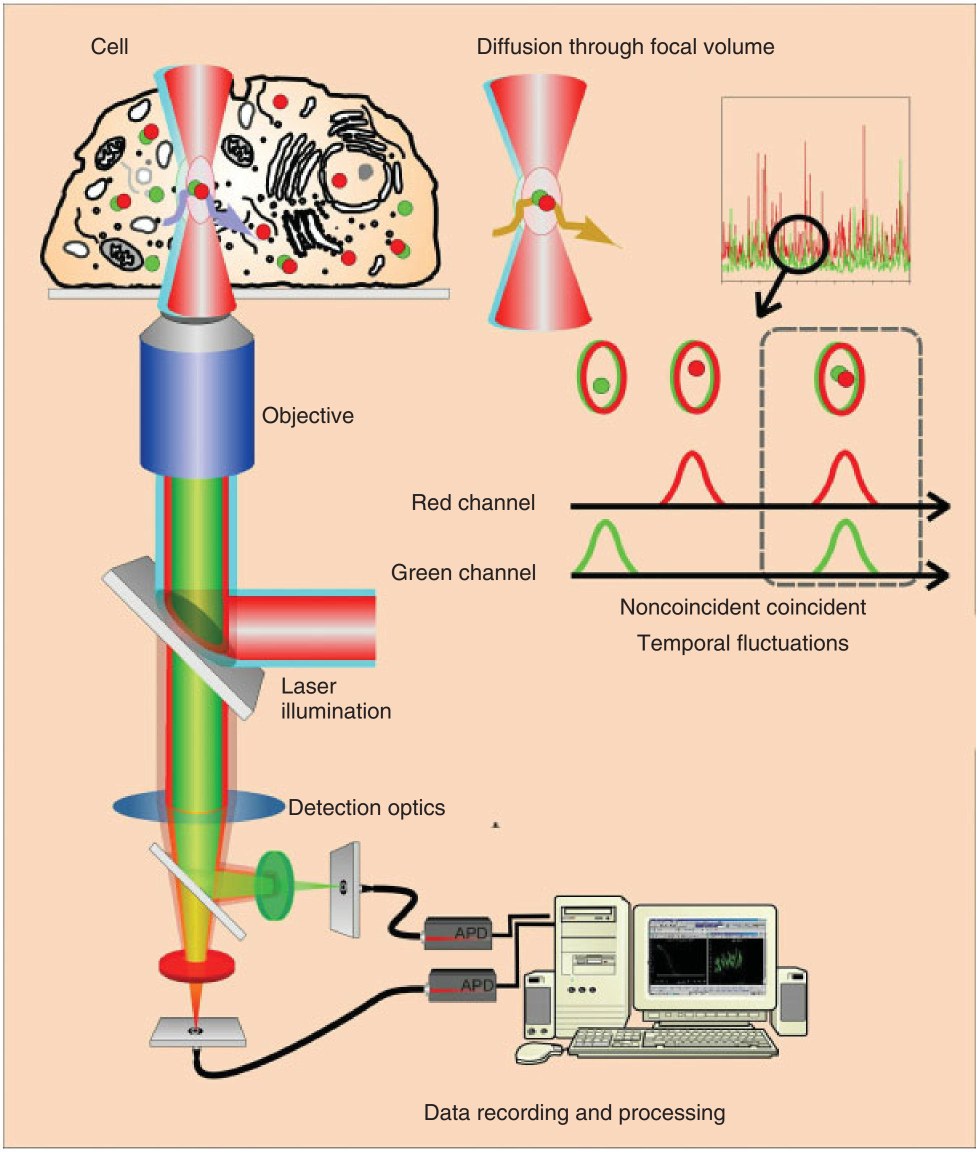

Figure 1 Principle of dual-color cross-correlation analysis for measurements in live cells: Concomitant movement of labels, which reflects molecular association of two different species, can be evidenced by coincident fluctuations in two different measurement channels. Hereby, protein–protein interaction can be probed in situ

fluorescence imaging, considerably improves cellular FCS applications. On the one hand, this is due to the dramatically reduced scattering and photobleaching in the spatially confined two-photon excitation spot, but also because of the broad absorption spectra for two-photon excitation of common probes (i.e., dyes with significantly different emission spectra can be simultaneously two-photon excited by the same infrared wavelength (Heinze *et al*., 2000)). This significantly

simplifies the optical setup, as only one excitation volume is now required. By this instrumental modification, two- or even three-color intracellular FCS applications are now possible, promising an enormous wealth of real-time studies on protein interaction patterns in situ (Kim *et al*., 2004).

A further and attractive application of dual-color cross-correlation has recently been proposed (Bacia *et al*., 2002). By following the diffusional movement of small endocytic vesicles with differentially labeled cargoes, various endocytic pathways can be distinguished and the preference of certain endocytosis mechanisms for different cargo species identified.

Combined with fluorescence resonance energy transfer (FRET), protein conformational dynamics can be addressable by FCS. This involves positioning the donor and acceptor dyes at opposite ends of a single protein. If reversible conformational changes occur on timescales that are fast compared to the observation time window, that is, the diffusion time of a molecule through the open focal volume, they can be dynamically analyzed by auto- and cross-correlation analysis (Margittai *et al*., 2003).

An interesting alternative to the standard confocal or two-photon excitation setup for sufficient background suppression in FCS applications, particularly on membranes, has been reported recently (Lieto *et al*., 2003). Total internal reflection (TIR) microscopy is a specific illumination feature that achieves extremely high axial resolution on the measurement volume to juxta-membrane regions. If laser light is incident upon a medium of lower refractive index under a critical angle, excitation will only occur in a thin surface layer of ca. 100 nm, the so-called evanescent field. In combination with a confocal pinhole for detection, unique resolution features can be obtained, and the separation of membrane-bound processes from fluorescent background in the solution above and below the membrane is facilitated. A combined TIR-FCS setup is particularly attractive to study the interaction of ligands with membrane-associated receptors, since it not only allows the user to distinguish free from bound ligand but also allows determination of binding and dissociation kinetics (i.e., a ligand can only be detected during its residence at the membrane where it is bound to the receptor).

Overall, it is fair to state that the era of cellular applications of FCS, as well as other single-molecule-based techniques, has just begun. A fascinating variety of applications are awaiting researchers in this special field of cellular biophysics. Presently, the bottleneck for these applications is not the optical technology but the availability of suitable fluorescence assays. Highly efficient site-specific fluorescent labeling of the molecule of interest, so minimizing the presence of unlabeled molecules and free dye, is often absolutely mandatory for quantitative studies. GFP technology with its broad palette of spectrally separable, genetically encoded probes certainly provides great promise for the development of multicolor assays. For example, GFP and its red homolog DsRed make a very good pairing for dual-color cross-correlation applications (Kohl *et al*., 2002). On the other hand, semiconductor nanoparticles such as "quantum dots" (*see* Article 57, **Quantum dots for multiparameter measurements**, Volume 5) may well provide a very attractive tool for FCS applications once their biocompatibility has been solved.

Short Specialist Review

Quantum dots for multiparameter measurements

Marcel P. Bruchez
Quantum Dot Corporation, Hayward, CA, USA

The optical properties of semiconductor nanocrystals are unique in fluorescence (Hotz, 2005; Bruchez *et al*., 1998; Chan and Nie, 1998). These particles are made from semiconductor materials at a size where the optical properties of the semiconductor are perturbed by quantum mechanical effects. This size range is known as the "quantum confinement" size regime. The emission spectra of high-quality quantum dots are very narrow (20–30-nm full width at half maximum), symmetric, and the emission color depends sensitively on the properties of the underlying particles, especially their size and composition. The absorbance of the particles is very large, typically 2–10 times any dye molecule at a single wavelength, and increases continuously at wavelengths shorter than the emission peak (see Figure 1). High-quality conjugated materials can be consistently prepared from blue to the near-infrared (450–900 nm), with quantum efficiencies of greater than 50%, resulting in the brightest fluorescently labeled biomolecules available. Because of the similar excitation properties for all colors of quantum dots, multiple colors can be efficiently excited simultaneously with a light source such as blue-violet filtered light or a 405- or 488-nm laser. Quantum dots are inorganic particles, and are well insulated from the environment, resulting in high photostability. This allows the materials to be tracked for many minutes to hours without any loss in fluorescence signal. The quantum dot materials provide a bright, sensitive family of easily distinguished fluorescent labels that can be imaged continuously for a variety of applications across biology.

Initial applications of these materials focused on labeling fixed antigens in cells and tissues with antibodies and biomolecules directly conjugated to quantum dots (Wu *et al*., 2003). Demonstrations of up to 5-color imaging with simple color filtering were easily performed with secondary detection using Qdot® conjugates to highly cross-adsorbed secondary antibodies (Figure 2). Such imaging with typical fluorophores cannot be accomplished without matrix unmixing of the fluorescent images owing to heavy overlap of the emission of the distinct dyes. Multicolor analysis of cells allows simultaneous imaging of morphological and functional parameters in a single cell, for instance, translocation and posttranslational modifications such as phosphorylation and glycosylation. In many cases, the state of a population of cells is just as interesting as the individual morphological

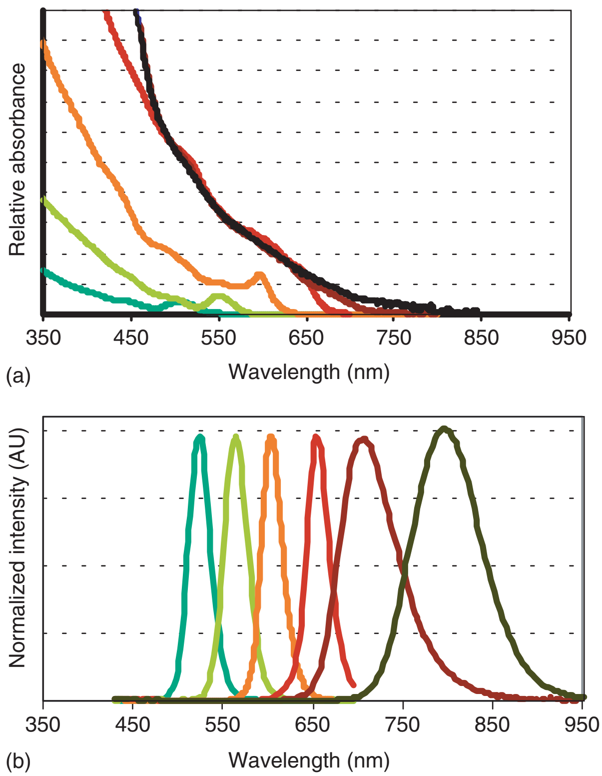

Figure 1 Absorbance (a) and emission (b) spectra of different color Qdot® conjugates

information. In these cases, quantum dots have been used for multiplexed western blotting, resulting in quantitative and sensitive multiprotein analysis in a single western blot. These applications are easily extended to investigate differences in protein expression and modification across a range of tissues and treated cells (Ornberg *et al*., 2005). Multiplexed quantitative analysis of protein modifications with quantum dots allows measurement of the activation of multiple pathways on fixed cells and cell lysates to determine signaling states. This returns more information than has been available from typical cellular analysis methods.

The photostability and brightness of the quantum dots provide investigators with new insights into receptor dynamics and ligand–receptor interactions in live-cell imaging (Dahan *et al*., 2003; Lidke *et al*., 2004). By labeling receptors with antibodies or with the native ligand, these groups discovered new dynamic properties of receptors at the cell surface that could not previously be observed. Dahan *et al*. demonstrated that single glycine receptors in the membrane of live neurons change their diffusion dynamics depending on the cellular site being sampled. At membrane sites away from the synapse, these receptors were highly mobile, though on diffusion into sites containing synaptic proteins they became pinned in place. By visualizing the diffusion of single receptors labeled with quantum dots for 20 min, these investigators were able to see these dynamics in

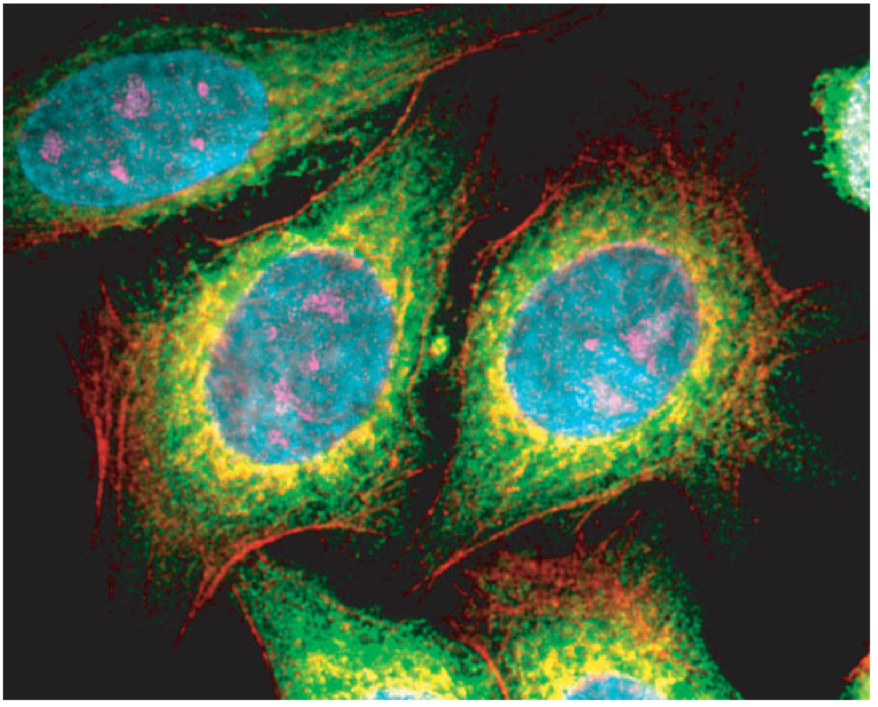

Figure 2 Multicolor immunolabeling with five colors of Qdot® conjugates. Fixed human epithelial cells were stained for Ki-67 (magenta, Qdot 605 anti-rabbit), nuclear antigens (cyan, Qdot 655 antihuman), mitochondria (orange, Qdot 525 anti-mouse), microtubules (green, Qdot 565 anti-rat), and actin filaments (red, Qdot 705 streptavidin). Individual gray scale images were captured with appropriate 20-nm bandpass emission filters, pseudocolored, and merged into a signal color image to show the relative cellular locations of the targets

real time with the knowledge that they were watching the behavior of a single molecule throughout the experiment. Previous studies had demonstrated that there were both highly mobile and immobile forms of this receptor, but they were unable to illustrate the key information that these two forms are the same receptor and that this is simply a context-dependent diffusion change. The ability to track biological events over physiologically relevant timescales is essential to the understanding of the roles of key biological components in signaling pathways, and quantum dots provide a nearly ideal tool for watching the interactions of extracellular components with the signal transduction machinery. Lidke *et al*. tracked quantum dot conjugated epidermal growth factor while interacting with a variety of visible fluorescent protein–tagged erb-B receptors in engineered cell lines. In doing this, they discovered new patterns of receptor dimerization and receptor–ligand trafficking in this important receptor tyrosine kinase family.

Recent applications of quantum dots in in vivo imaging have demonstrated the utility of quantum dots for noninvasive molecular analysis in living animals (Akerman *et al*., 2002; Ballou *et al*., 2004; Kim *et al*., 2004; Voura *et al*., 2004; Gao *et al*., 2004). These investigators demonstrated how quantum dots can be

designed to escape the reticuloendothelial system and can be used to track cells and to label vascular structures. In addition, these materials can target to cell surface antigens or vascular surface markers when conjugated to a targeting antibody or peptide. The strong absorbance and photostability of near-infrared-emitting quantum dots enable the detection of tissues and structures deep in animals, and suggest potential applications in diagnostics, surgery, and biological research. In addition, the ability of high-quality quantum dots to survive embedding, fixation, and typical tissue mounting procedures allows researchers to monitor their experiments noninvasively and subsequently perform detailed tissue analysis and molecular colocalization experiments.

The multiple colors provided by various sizes of quantum dots are currently being exploited in combination to create massively multiplexed systems of cells or beads for parallel analysis (Mattheakis *et al*., 2004; Han *et al*., 2001). Color combinations on beads can generate the spectral equivalent of a bar code, which, when coupled with distinct reporters, allows simultaneous analysis of many analytes in a sample (Figure 3). Initially, this capability was demonstrated with simple hybridization, and for multiplexed single nucleotide polymorphism analysis (Xu *et al*., 2003). This strategy has been developed into a system for multiplexed mRNA analysis and commercialized as the Mosaic™ Gene Expression Assay System by Quantum

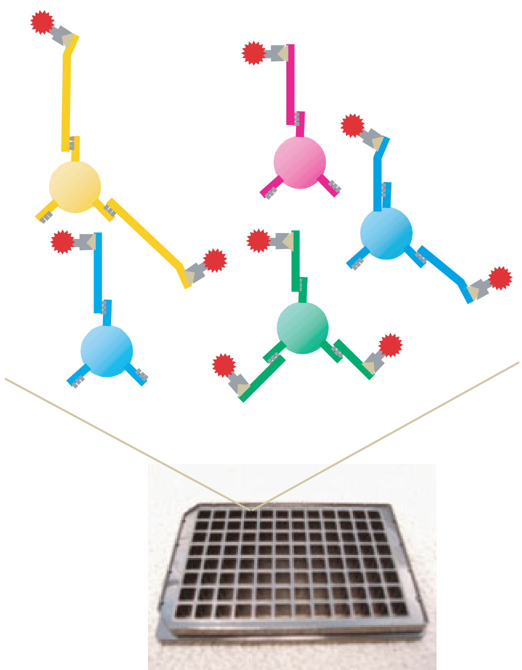

Figure 3 Schematic overview of a Mosaic™ gene expression assay. Beads with different spectral fingerprints are shown in different colors, and are attached to unique sequences. These are hybridized to the mRNA from a sample, and then quantitatively detected with a distinct color. This system is suitable for quantitative analysis of many genes in many samples in a multiwell plate format

Dot Corporation. The key advantage of this system is the large number of codes available. With room for plenty of distinct codes, a large number of internal controls and a high level of replication can be built into the system, allowing statistically valid, robust, and precise measurements to be performed. Building the appropriate quality control into each assay ensures that all of the assay steps are successful. This results in consistently meaningful data, with less time spent duplicating experiments. This level of gene expression analysis allows researchers to reproducibly and quantitatively compare hundreds of genes over thousands of samples.

Quantum dots are an enabling tool for modern fluorescence-based biology, and are poised to help researchers answer many questions raised by newly available proteomic and genomic information. The practice of following single markers has given way to the analysis of multiple cellular systems, along with upstream, downstream, and off-target effects, requiring more information per experiment. When multiplex capability, sensitivity, and stability are needed for looking at proteins or genes in live cells, fixed cells, tissues, animals, or other samples, quantum dot–based probes have pointed researchers to new questions and have given them new tools to get the answers.

Basic Techniques and Approaches

Immunofluorescent labeling and fluorescent dyes

Peter Watson, Krysten J. Palmer and David J. Stephens
University of Bristol, Bristol, UK

1. Introduction

Immunofluorescence microscopy is an important experimental tool for investigating the distribution of soluble and structural proteins within cells. This technique can give clues to the function of a poorly understood protein and enable direct comparisons of a protein's localization in various cell types and tissues at different stages of the cell cycle, during development or under stress or stimulation. Successful immunofluorescence requires fixation and permeabilization conditions that preserve the in vivo distribution of the protein(s) under examination. The quality of antibodies used is critical to ensure both specificity and high signal-to-noise on detection. Choice of direct versus indirect methods, amplification method if any, fluorescent dye conjugate, and detection method will all determine the success of immunofluorescence experiments, and careful consideration needs to be given to each. The complexity of protocols employed will also largely determine the applicability of the methods to high-throughput analyses. We also consider the application of technologies that, although not commonly employed at present, have great potential for the future; these include the use of recombinant antibodies and immunofluorescence in the context of live cell imaging. Here, we discuss the possible approaches and highlight some of the pros and cons of their use in the specific detection of molecules in cells and tissues.

2. Fixation protocols

The main aim of fixation is to freeze a sample in a state that is as close to "real life" as possible. In essence, this would render immunofluorescence impossible, as the cell membrane creates an effective barrier to this approach, and so certain compromises must be made between keeping cellular structures intact and having a working specimen in which to identify those structures. Soluble proteins have the unfortunate tendency to redistribute and/or become differentially extracted, while membrane proteins and cytoskeletal elements are subject to a lesser change.

Fixation and permeabilization methods must therefore be carefully selected and best suited to the protein(s) in question, considering size and charge as well as cell structure and type. Critical to the application of immunofluorescence to proteomic experiments is the reproducibility of the fixation technique used and indeed of the entire labeling protocol. One must ensure reproducibility across a large number of samples, particularly for comparative analyses of protein localization or readouts of cell function.

The two main processes of cellular fixation for subsequent immunofluorescence are chemical cross-linking (e.g., paraformaldehyde or glutaraldehyde) or protein precipitation by an organic solvent (e.g., methanol or acetone). The quality of cellular structures that remain following fixation can vary, depending on the method of fixation and the initial cell type used, and so this must be kept in mind. Excellent discussions of fixation methods can be found in Allan (1999) and Melan and Sluder (1992).

Aldehyde cross-linking forms methylene bridges between side groups. Formaldehyde (or paraformaldehyde) is most commonly used for immunofluorescence microscopy as it is readily available and is soluble in water. Glutaraldehyde was first used as a fixative for histological EM (electron microscopy) studies (Sabatini *et al*., 1963) and preserves internal structures well, presumably due to its ability to cross-link neighboring protein molecules via its two reactive groups. However, glutaraldehyde fixation may be problematic for immunofluorescence owing to an observed increase in autofluorescence of the sample and an inability of the antibody to reach the desired epitope because of the strong cross-linking effect. Other fixatives including ethylene glycol bis(succinimidylsuccinate) and dithiobis(succinimidylproprionate) are less commonly employed as they are poorly soluble in water. Both provide excellent fixation of microtubules and membranes and maintain antigenicity of many glutaraldehyde sensitive epitopes (Allan, 1999).

Permeabilization of chemically cross-linked cells is necessary for access to internal epitopes. Triton X-100 (0.1%) is regularly used as a nondenaturing detergent to permeabilize the cell membrane. Digitonin and saponin are also used. Analysis of a range of concentrations of these detergents is best to determine empirically the ideal conditions for a particular experiment. If the antibody only recognizes a denatured epitope, an incubation step with a denaturant (i.e., guanidine hydrochloride) can be included.

The most widely used alternative to aldehyde fixation is the use of organic solvents. Solvent fixation is very quick, and has the advantage of needing no permeabilization step or quenching of unreacted chemicals following fixation. Many intracellular structures are better preserved following one or other method, and similarly, antigenicity can be different following each method. Consideration must also be given to whether a particular fixation method might redistribute an antigen with a cell. Detailed protocols for most of these techniques can be found in Allan (1999).

3. Generating antibodies

Polyclonal, monoclonal, and recombinant antibodies all have their relative merits and disadvantages. An excellent discussion of antibody production methods

for proteomics can be found elsewhere (Bradbury *et al*., 2003a). Successful immunofluorescence is wholly dependent on the specificity of the primary antibody used. In all experiments, titration of each preparation of antibody is important in order to determine the optimal concentration for fluorescence microscopy. Polyclonal antibodies often provide enhanced signals compared to monoclonal equivalents in immunofluorescence, and affinity purification can ensure high specificity. Polyclonal antibodies are also cheaper to produce and can be readily made in sufficient quantity for most purposes. However, unlike with monoclonal antibodies, the continued supply necessary for long-term projects is not guaranteed. Although an antibody may work for immunoprecipitation or immunoblotting, it does not automatically follow that it will be suitable for immunofluorescence. Optimally, a number of antibodies to different epitopes on the same protein are compared in order to identify the most suitable for immunofluorescence.

4. Recombinant antibodies

The generation of recombinant antibodies using phage display technology is now relatively simple and can be readily scaled up using high-throughput technology (Hust and Dubel, 2004). The process involves the selection and purification of recombinant antibody fragments (single chain fragment V, scFv). A library of antibody fragments presenting bacteriophage undergoes several rounds of affinity selection (panning) against the protein of choice (Figure 1(a) shows an example of panning for antibodies directed against the small GTPase, Rab6). Once a bacteriophage with a positive antibody fragment has been identified, the antibody fragment can be expressed and purified, effectively in unlimited quantity. The simplicity and speed of this approach also makes it amenable to the production of conformation-specific antibodies directed against a single protein (Nizak *et al*., 2003), for example, one that preferentially recognizes the GTP-bound form of Rab6 and has a low affinity for the GDP-bound form (Nizak *et al*., 2003). These antibodies are suitable for immunofluorescence (Figure 1b and d show specific localization of Rab6GTP to the Golgi, consistent with its known function). Immunofluorescence need not be restricted to fixed cells and combining recombinant antibody and green fluorescent protein (GFP) technology permits the use of these reagents in live cell imaging experiments (Figure 1c) (Nizak *et al*., 2003). Thus, antigens can be observed in situ without the need to fix and permeabilize cells and eliminating the need for secondary detection.

There is a greater chance of finding antibodies to a selected epitope, and an increased chance of selecting a high affinity epitope, as the size of the initial phage library increases; this underlies the key limitation of the technology. Higher affinity antibodies can be created by mutation of the initial isolated phage followed by further rounds of selection. The potential of this approach, particularly for large-scale proteomic approaches (e.g., its use as a fluorescent biosensor) is huge, and will doubtless undergo considerable development in future years.

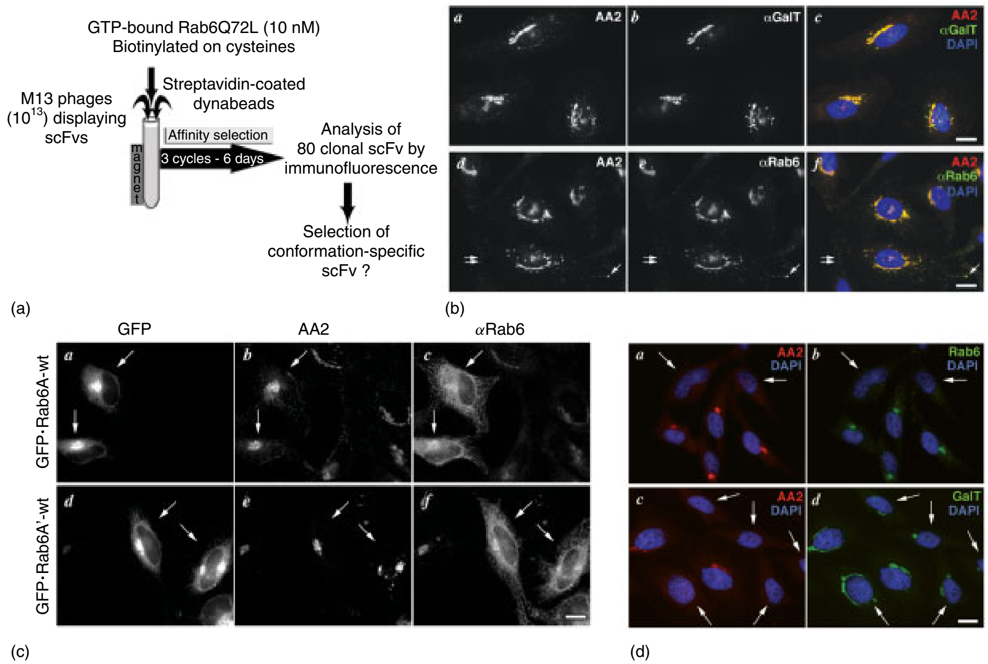

Figure 1 Recombinant antibodies for immunofluorescence. (a) The production of specific recombinant antibodies is achieved by sequential panning of a phage library against a subcellular fraction or protein of interest (here, recombinant Rab6-GTP). (b) This allows localization of endogenous proteins in living, unfixed cells. Here, antibody AA2 shows specific localization of endogenous Rab6-GTP to the Golgi as shown by colocalization with galactosyltransferase (GalT). (c) These antibodies can be produced such that they recognize only specific conformations of a target protein, here, the GTP-bound conformation of the small GTPase Rab6. Differential localization of total versus GTP-bound pools of Rab6 using a GFP fusion of AA2. (d) Specificity is confirmed by showing a loss off immunofluorescent labeling after depletion of Rab6A using RNA interference (Reprinted with permission from Nizak *et al*. (2003). Copyright (2003) AAAS)

5. Secondary antibodies

Most frequently, immunofluorescence is performed indirectly; that is, the primary antibody used is detected by a separate fluorescently labeled secondary antibody. There are three main considerations for the secondary antibody: the species that it was raised in, the level of cross adsorption against other species it has gone through during the purification process, and the fluorophore that it is linked to. Cross adsorption against other species reduces the possibility of spurious recognition of other antibody preparations used for colabeling, and should result in lower background binding to your chosen cell type. Careful choices need to be made depending on host species for the generation of these antibodies. For example, use of primary antibody raised in the goat would preclude the use of secondary antibodies raised in the same species. Fortunately, major manufacturers provide suitable solutions to this through the availability of antibodies raised in the goat and the donkey.

6. Choice of fluorescent dye

Direct immunofluorescence can be done by conjugating primary antibodies (whole molecules or Fab' fragments) directly to fluorophores. Many manufacturers provide kits to achieve this through succinimidyl esters, isothiocyanates, sulfonyl chlorides, tetrafluorophenyl esters, or thiol-reactive probes. Tetrafluorophenyl esters produce stable carboxamide bonds and are less susceptible to hydrolysis than succinimidyl esters. Isothiocyanate conjugates deteriorate over time. Similarly, these reactive groups are used to conjugate dyes to secondary antibodies for indirect immunofluorescence.

For multiple labeling experiments, the fluorophore used depends upon limiting the crossover between emission spectra, and the visualization methods (i.e., the excitation and emission filters) that can be used. New approaches to spectral separation through hardware and software developments (Zimmermann *et al*., 2002) are now enabling the simultaneous analysis of more and more probes in a single cell or tissue. These techniques are applicable to both confocal and wide-field imaging.

Previously, commonly used dyes such as fluorescein and rhodamine suffered from low quantum yield (brightness) and rapid photobleaching. Newer dyes such as the Alexa Fluor dyes from Molecular Probes or cyanine dyes (CyDye Fluors) from Amersham Biosciences are more photostable than previously used dyes such as fluorescein isothiocyanate (FITC). This allows repeated viewing, time-lapse imaging of living cells, and the production of three-dimensional (3D) data sets with reduced photobleaching. Conjugation at high molecular ratios of the fluorophore to the protein can lead to fluorescence quenching, presumably owing to dye–dye interactions (Randolph and Waggoner). It is possible to attain a higher dye-protein ratio with the Alexa Fluor dyes before quenching becomes noticeable (Berlier *et al*., 2003). These dyes are also available with a diverse array of spectral characteristics, permitting the use of two, three, four, or more dyes simultaneously.

It is now possible to combine the simplicity and flexibility of fluorescent imaging by light microscopy with the ultrastructural resolution provided by electron microscopy (EM). This can be done using a combination of GFP and immunogold labeling (Mironov *et al*., 2000) or through the use of probes such as Fluoronanogold that contain both fluorescent labels for light microscopy and a Nanogold cluster for EM (Takizawa and Robinson, 2000). The use of the Nanogold label avoids the problem of fluorescent quenching seen with colloidal gold conjugates. (For further information, see **http://www.nanoprobes.com**.) The labor-intensive nature of EM means its use in proteomic experiments is likely to be limited.

7. Quantum dots

Quantum dots (Qdots) consist of a semiconductor nanocrystal core, a semiconductor shell, and a polymer coat (Seydel, 2003) and are fluorescent as a result of the quantum confinement effect. The polymer coat can be conjugated to biomolecules, including streptavidin and antibodies, allowing binding specificity while retaining the optical qualities of the crystal (Chan and Nie, 1998). Qdots are stable and

nontoxic inside the cytosolic compartment (Dubertret *et al*., 2002), and can be used for immunofluorescent labeling of cells and tissues (Wu *et al*., 2003; Jaiswal *et al*., 2003). A key problem with quantum dots is their bioincompatibility (high nonspecific binding to the sample) and physical size. Qdots are discussed in more detail elsewhere in this volume (*see* Article 57, **Quantum dots for multiparameter measurements**, Volume 5).

8. Image acquisition and high-throughput technologies

Imaging of fluorescent samples can be done in a number of ways including scanning confocal microscopy and wide-field imaging (see Stephens and Allan, (2003) for a review) as well as flow cytometry. Imaging of multiple fluorophores, time-lapse imaging and multidimensional imaging (3D and 4D), deconvolution, and image reconstruction can all add significantly to specific experiments and these topics are dealt with elsewhere in this section. Immunofluorescence labeling and detection are highly amenable to automation scaled to 96- or 384-well formats (Bradbury *et al*., 2003b). Robotic handling can be applied to the fixation and labeling steps, and automated object recognition algorithms (Liebel *et al*., 2003; Danckaert *et al*., 2002) now permit the detection of subcellular localization across a population of cells. A recent example is the assembly of a system for rapid automated screening of cDNAs (Liebel *et al*., 2003), which has been applied to high content screening of processes such as intracellular traffic using immunofluorescence to define protein function.

9. Summary

The application of immunofluorescence toward diagnostics and studies of protein function depend largely on reliable, reproducible methodologies. The development of antibody chips will facilitate much wider analyses of protein function on a proteomic scale, and these can also be used for immunofluorescence localization (Wang, 2004). The possibilities of recombinant antibodies, live cell imaging, high throughput, and high content screening mean that immunofluorescence of both fixed and living cells will continue to be a valuable tool to define protein function.

Quantitative image analysis and the Open Microscopy Environment

Jason R. Swedlow, Chris Allan, Andrea Falconi and Jean-Marie Burel
University of Dundee, Dundee, UK

1. Introduction

Microscopy has traditionally been a technique devoted to understanding the structure and dynamics of the cell. The combination of genetically encoded fluorescence based on fluorescent proteins (Tsien, 1998; *see also* Article 50, **Using photoactivatable GFPs to study protein dynamics and function**, Volume 5) and the availability of easy-to-use digital imaging systems has revolutionized applications for microscopy in modern biology. A vast array of imaging modes is already available, with more on the way (*see* Article 48, **Probing cellular function with bioluminescence imaging**, Volume 5, Article 51, **FRET-based reporters for intracellular enzyme activity**, Volume 5, Article 54, **Probing protein function in cells using CALI**, Volume 5, Article 55, **Imaging protein function using fluorescence lifetime imaging microscopy (FLIM)**, Volume 5, Article 56, **Elucidating protein dynamics and function using fluorescence correlation spectroscopy (FCS)**, Volume 5 and Article 57, **Quantum dots for multiparameter measurements**, Volume 5). Most critically, microscopy is not just visualization, or "seeing", but now also quantification, often at the molecular level (Gerlich *et al*., 2001; Swedlow, 2003). Quantitative imaging can be used to characterize the signal and noise characteristics of different microscopes (Murray, 1998; Swedlow *et al*., 2002; Zucker and Price, 2001), and it also allows image-based assays, where the localization and movement of macromolecules can be measured in fixed and living cells (Lippincott-Schwartz *et al*., 2001; *see also* Article 53, **Photobleaching (FRAP/FLIP) and dynamic imaging**, Volume 5 and Article 56, **Elucidating protein dynamics and function using fluorescence correlation spectroscopy (FCS)**, Volume 5). Taken to the extreme, image-based assays can be expanded to assay the effects of libraries of small molecule inhibitors (Yarrow *et al*., 2003; Straight *et al*., 2003), or libraries of genes or even whole genomes (Simpson *et al*., 2000; Kiger *et al*., 2003; *see also* Article 52, **High content screening**, Volume 5).

A major problem in these assays is the systematic analysis of the large amounts of data that are produced. There are two parts to this problem. First, data must be stored in a secure and accessible fashion, with redundant backups. Second, while there is much emphasis on developing image acquisition systems and analysis algorithms for cell-based assays, systematic analysis requires an informatics infrastructure that maintains relations between binary image data, experimental and image metadata, and any processing and analytic results. In this article, we discuss our efforts toward both of these goals.

2. Secure and available storage of image data

Historically, high-density fixed storage devices have not been affordable by most academic laboratories, so most image data storage has been stored on whatever high-density removable media devices were available. For instance, various optical disc formats were available during the late 1980s and these provided a convenient method for storing data. Unfortunately, the formats used for these devices became obsolete within a few years, and archived data effectively was lost on unreadable media. More recently, compact disks (CDs) and digital versatile disks (DVDs) have been used; however, these are not permanent media and usually are not indexed with the files they contain. The result is usually a mass of unindexed archived data, spread across a large number of CDs or DVDs. When students leave a lab, these collections of disks and all their precious data are placed in a box and stored, often in the principal investigator's office, to gather dust as the media steadily degrades.

Recently, large-scale data storage and archiving systems have become available and it is now possible to purchase multiterabyte data storage systems at reasonable cost. However, just like any other data storage medium, these systems have fixed capacity and, therefore, will eventually fill to capacity. Scalability is a crucial consideration to ensure that management burden and costs do not also scale each time the storage system is expanded.

To solve this problem, we have employed a hierarchical storage system, consisting of separate pools of storage media with different price/performance ratios that ensure that the most recently acquired and accessed data is immediately accessible. An automatic archiving system checks the on-line filesystem every five minutes for all files that have not been accessed after a certain date and moves everything except the first 0.5 MB of the file off to a tape archive. Migrated files are still visible in a user's directory, and are automatically returned from the archive if accessed. Files that are either forgotten or never used are then automatically archived on more cost-effective media. While this strategy involves a time penalty for infrequently accessed files (data transfer only requires a few seconds for >500 MB, but finding and loading tapes can take up to 90 s), the advantage is that on-line filesystem space is reserved for actively used files. Moreover, if systems are bought strategically, the different storage media pools can be expanded where it is necessary to expand the overall capacity of the storage system. On-line disk arrays currently cost \$3000–12 000/Tbyte, while tape storage or lower performance disks cost \$100–500/Tbyte. While any efficient storage system will include a facility for a "permanent" archive to off-line storage, the hierarchical approach that we have implemented allows data

to be kept available for analysis and further experiments at a price that is affordable by most laboratories. A diagram of our system is shown in Figure 1.

It should be noted that the infrastructure to use such a solution requires a significant up-front investment for servers, fiber channel switches, and so on, and significant expertise for configuration. *The most important investment we have made is in the skilled personnel to run these facilities!!!*

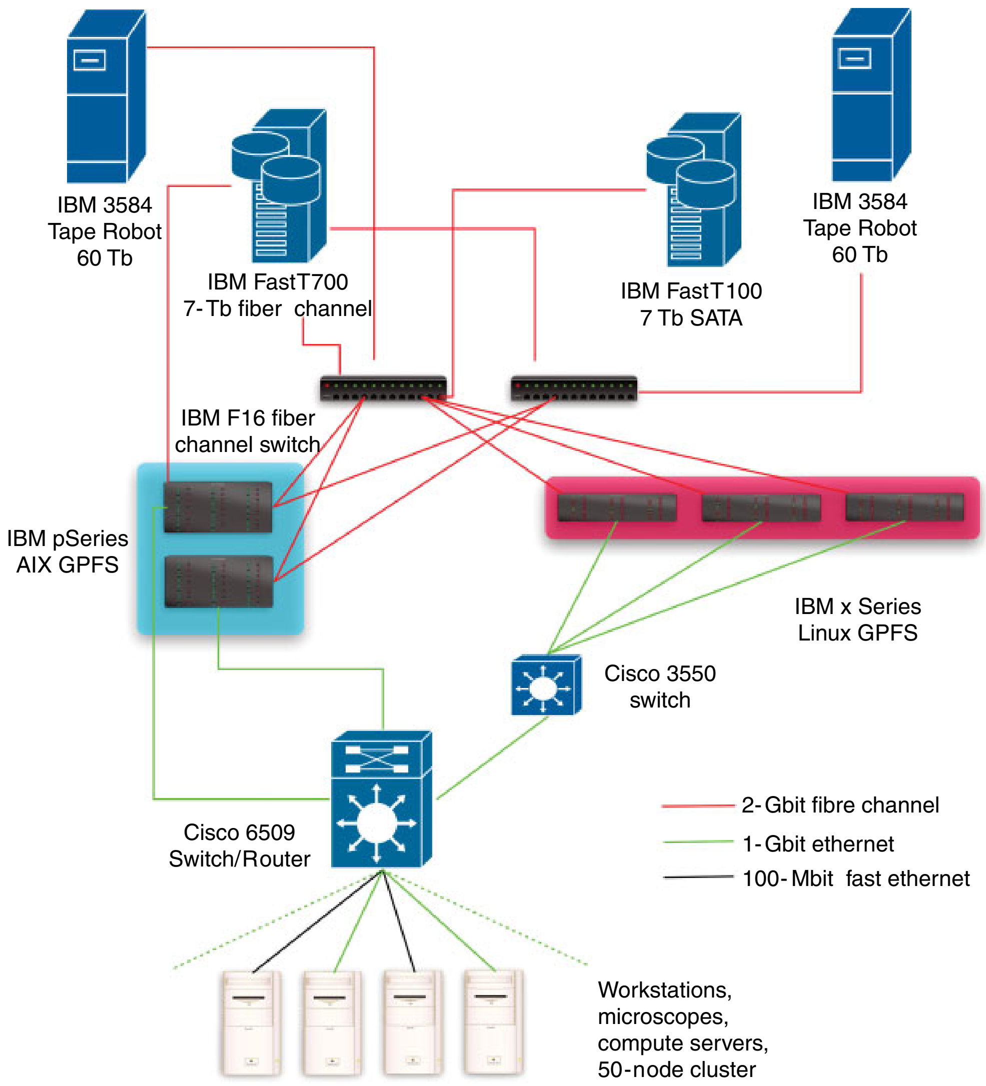

Figure 1 Hierarchical data storage system. The general layout and infrastructure of the Light Microscopy Facility data storage system at the Wellcome Trust Biocentre, University of Dundee. The specifics of network connections and redundancy and hardware configuration are not included for clarity. The hierarchical file management is run by Tivoli Storage Manager. Most of our storage equipment is provided by IBM, but similar solutions are available from other vendors. The types of network connections between the different hardware devices is indicated

3. Toward image informatics – the Open Microscopy Environment

Biological image data is "content-rich": the distribution of biological molecules are recorded, usually within the context of spatial location at a specific time, and often relative to the distribution of at least a few other molecules. Methods that measure the environment of a fluorophore, its binding affinity, molecular interactions, and chemical neighborhood only add to this complexity. Unlike genomic data, where the output of a DNA sequencing system ("... GAGCTC ... ") directly identifies a specific sequence, the mapping of image pixel values to a "result" requires much more contextual knowledge – the contrast method of imaging (e.g., fluorescence, DIC, etc.), the mode (e.g., fluorescence lifetime, resonance energy transfer, etc.), and large numbers of descriptors about the structure of the data (e.g., time lapse, illumination, objective lens) (Andrews *et al*., 2002). Given the pace of methodology and application development in biological imaging, it has been impossible to develop a single data format standard that would support the needs of the whole field. More fundamentally, an "image" is only a small part of the data relevant to an imaging experiment. Knowledge of the experiment (cell type, mutant, staining method, etc.) as well as the results of any analyses (rates, intensity changes, etc.) all represent critical measurements that must be linked to all other data elements. Without these links, loss of one data element (e.g., the cell line used for a specific image, the time lapse interval) can invalidate all of the data related to it.

To solve this problem, we are building an open-source image data, metadata, and analysis management system known as the Open Microscopy Environment (OME; **http://openmicroscopy.org**) (Swedlow *et al*., 2003). OME is specifically designed for the storage and analysis of digital microscope image data and metadata. The major focus of OME is not on creating novel analysis algorithms, but instead on development of a structure that ultimately allows any application to read and use any data associated with or generated from digital imaging microscopes. The critical role for metadata and analytical results in biological imaging is discussed in more detail elsewhere (**http://openmicroscopy.org/applications**). OME is designed for installation to support the work in a single lab or imaging facility, although there are larger use cases suggested by others to support the centralized provision of large numbers of images to the research community (Schuldt, 2004).

The heart of the OME system is the OME Data Model, which provides the framework for all the data relationships managed by OME. This model is instantiated in two ways. The OME XML File casts the OME Data Model into a self-describing entity using XML, the standard methodology for providing access to data. The Data Model and the XML file are both described at **http://openmicroscopy.org/api/xml/** and are the subject of a future publication. In addition, the Data Model is the foundation of a data warehousing, management, visualization, and tracking system, known simply as "OME", the basic layout of which is shown in Figure 2 (see Swedlow *et al*., 2003 for more info). A key concept in our implementation is the possibility for local extensibility. A number of basic data elements will be shared between all data (User Name, Image Dimensions, etc.), but local customization will always be required. The use of XML intrinsically supports this extensibility such that the Data Model, the OME XML File, and an instantiation of OME software

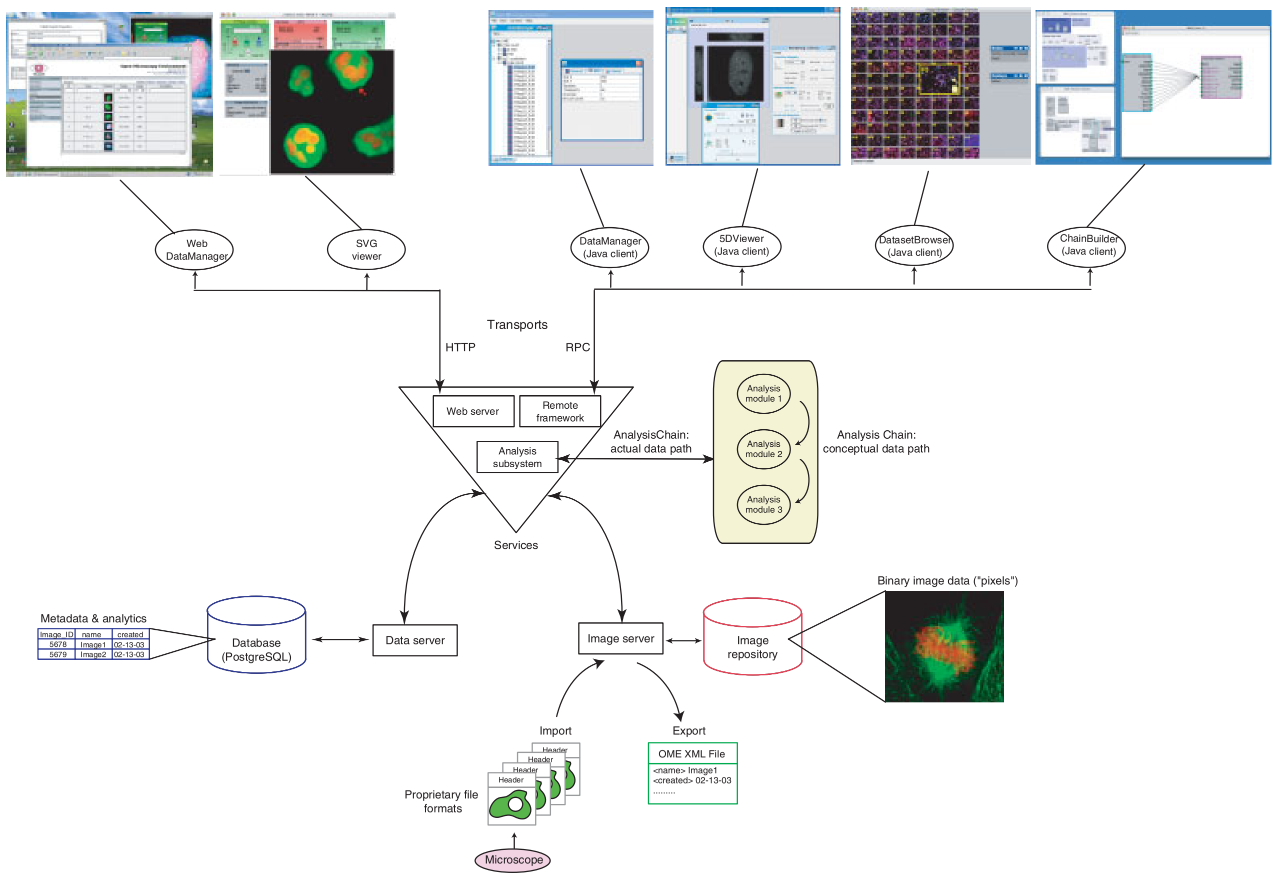

Figure 2 General layout of OME. A diagram showing the different parts of the OME server and interface systems. This figure is not a software architecture document and serves only to define the general functionality of the system. Imported data from a microscope system is stored within a database and an image repository (see text). The OMEIS and OMEDS servers manage all access to the image repository and database, respectively. Data is accessed for visualization and analysis via a services layer that supports HTTP and XML-RPC. Currently, OME2.2 is distributed with support for web browser access and a stand-alone Java-based image visualization and analysis tool ("Shoola") and a DatasetBrowser for viewing large groups of images. Screenshots of these tools are shown at the top of the figure

can all be updated to adapt to specific needs. The details of this are described at **http://openmicroscopy.org/api/xml/**.

In our current system, OME2.2 (**http://cvs.openmicroscopy.org.uk**), image data is imported from a user's microscope using OME tools that read specified commercial file formats. OME considers an "image" as a five-dimensional data structure (space, time, and channel) (Andrews *et al*., 2002). All relevant metadata is recovered from the user or the incoming data file and entered into the database using the OME Data Server (OMEDS). The actual pixel values form a large amount of data and are stored separately in a specified, protected filesystem, the OME Repository, and accessed through the OME Image Server (OMEIS). OMEDS and OMEIS can exist on the same or different servers as necessary. During import, a large number of statistical measurements (e.g., minimum, maximum, and mean pixel values) are performed and stored in the database.

All access to the data within OME is made through a transport layer that supports a variety of access methods. Data visualization and management using a web browser are supported using standard HTTP protocols. A more flexible interface is provided using "Shoola" and OME-JAVA, application programming interfaces (APIs) that support access from Java remote client programs. More general access to the OME Services is provided over XML-RPC. To take advantage of these systems, we have also built a number of Java-based client applications that provide cross-platform access to OME for visualization, data management, and analysis. Examples of the web browser and Java interfaces are available at **http://openmicroscopy.org/getting-started/**.

A major focus for OME is the integration of image processing and analysis into a single data model. This affords a significant convenience in that all data pertinent to an experiment is maintained in a coherent or linked manner. More profoundly, this approach generates a transactional record of all processing and analytic events that occur on an image. In practice, OME captures all of the input and output parameters for an analysis, as well as the specific results – a new image, rates, sizes, and so on. Each analysis event is uniquely identified, so that the consequences of each analysis, and each parameter change for a given analysis, can be accessed.

4. Image informatics and OME – the future

The OME project was initiated simply on the basis of a need for large-scale data management that no one else had filled. In the past two years, the OME project has successfully transformed from a prototype system – OME1.0 – to a fully integrated multisite open-source software development project. There are currently eight full-time developers working on OME at the University of Dundee (Dundee, UK), National Institutes of Health (Baltimore, USA), Massachusetts Institute of Technology (Cambridge, USA), Deutsches Krebsforschungszentrum (Heidelberg, Germany), and the University of Wisconsin, Madison (Madison, USA) (see **http://openmicroscopy.org/about/**). All work is coordinated through a CVS server running at the University of Dundee (**http://cvs.openmicroscopy.org.uk**). The project has met a number of milestones over the last two years, released in two

major releases, OME2.0 (released June 2003) and OME2.2 (released June 2004), with our final release in this series, OME2.4, scheduled for March 2005. These releases will finish our initial efforts to define what an image data management tool can do. For the last six months, OME2.2 has been tested with real use cases covering large-scale image assays for cell biology and high-throughput screening. These tests have shown the founding concepts and implementation in the OME Data Model to be sound, but have revealed a number of limitations to the system. For example, the current version of OME only supports very limited abilities to delete data, once it exists within OME. This has been deliberate, as the model and implementation errs on the side of caution on this issue. Nonetheless, there are real cases where data can be archived and then deleted from a database, and this functionality must be supported. More generally, our interface and server structure has been designed as an initial prototype. With our current testing experience, there are now clear avenues for substantially improving the performance of the system, and the project will begin implementing these changes in 2005.

In the future, OME can serve as a data management service for single labs and as a portal to a Grid-enabled data management network. This technology promises to share data, processing algorithms, and processing power across many different sites. While the tools for these ideas are still developing, OME's provision of a managed data system at a lab or imaging facility will provide the basis for a larger network of image data sharing and analysis.

Acknowledgments

We gratefully acknowledge helpful discussions with our academic and commercial partners (Swedlow, 2004) and members of the Swedlow laboratory. Research in the authors' laboratory is supported by a grant from the Wellcome Trust (Ref 068046 to J. R. S.). J. R. S. is a Wellcome Trust Senior Research Fellow.

siRNA approaches in cell biology

Alexandra Gampel and Harry Mellor
University of Bristol, Bristol, UK

1. Introduction

Small interfering RNAs (siRNAs) allow for the targeted silencing of gene expression in cultured cells and whole organisms. The simplicity of the technique allows it to be applied to the analysis of whole genomes and, when coupled with recent advances in microarray screening and proteomic techniques, siRNAs provide an incredibly powerful tool for postgenomic research. It seems clear that siRNAs will play a key role in biological research in the coming decade. Here, we review the basis of the technique and examine some of the key uses to which it is being applied.

2. Mechanisms of action

Scientists have known that double-stranded RNA is a powerful mediator of targeted gene suppression for some time (Fire *et al*., 1998). This technique has been exploited by the *Caenorhabditis elegans* and *Drosophila* research communities to allow routine silencing of individual genes, as well as genome-wide screening protocols. One major limitation of this technique, however, was its lack of application to mammalian cells. In mammalian cells, double-stranded RNA triggers a number of innate defense mechanisms designed to counter viral infection (Samuel, 2001). So, while double-stranded RNA is effective in gene silencing in mammalian cells, the toxicity of these others responses makes this procedure unfeasible in practical terms. The breakthrough discovery was made recently by Tuschl and colleagues, who showed that small, 21–25 nucleotide double-stranded RNAs were capable of mediating gene silencing in mammalian cells without invoking the toxic antiviral responses (Elbashir *et al*., 2001a). The basis for this finding has become clearer with the elucidation of the mechanisms of siRNA action (Figure 1; reviewed in (Hannon, 2002)). In multicellular eukaryotes, double-stranded RNA is targeted by the enzymes of the Dicer family of class III ribonucleases, which process RNA into short, ∼22 nucleotide double-stranded RNA oligonucleotides. These short RNA duplexes are then bound by the RISC (RNA-induced silencing) complex, which discards one strand and uses the other to seek a complementary target mRNA. Having found its prey, the nuclease activity of RISC

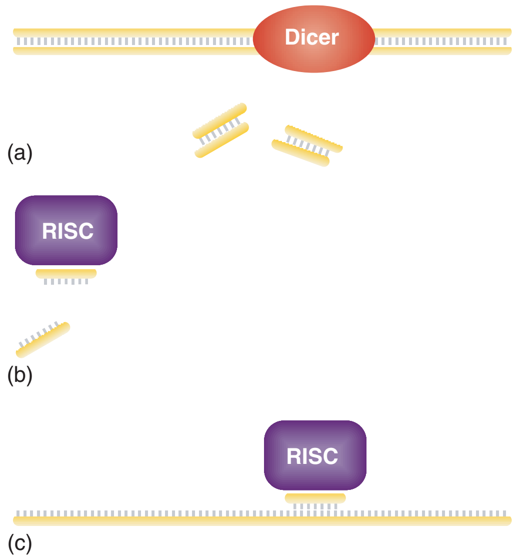

Figure 1 A model for siRNA action. (a) dsRNA is targeted by class III ribonucleases of the Dicer family, which bind as a dimer and fragment the template into siRNAs – short, double-stranded oligonucleotides of approximately 21 nt in length, with 2 nt overhangs at the 3′-ends. (b) The siRNAs are bound by the RISC complex, whose intrinsic helicase activity separates the strands and discards one, keeping the other as a guide RNA. (c) The RISC complex binds to target mRNA with high specificity through Watson–Crick base pairing with the guide RNA. The endonuclease activity of the RISC complex then degrades the target. Synthetic siRNAs are used directly by the RISC complex, sidestepping Dicer, and also avoiding activation of the antiviral response, which requires longer dsRNA

then degrades the mRNA, leading to functional silencing of gene expression. Short synthetic siRNAs are effective substrates for the RISC complex, but are too short to activate effectors of the toxic antiviral response such as the PKR kinase. By feeding straight to the RISC complex, siRNAs allow for effective gene silencing in mammalian cells with little or no toxicity.

3. Design and delivery

One major advantage of siRNA mediated gene silencing is how few constraints there are in the design of successful reagents; a marked contrast to antisense technologies. In our experience, approximately 30% of siRNAs will mediate significant silencing when chosen solely on the basis of annealing temperature. Ongoing research into the mechanisms of siRNA action has already identified criteria that determine the specificity (Elbashir *et al*., 2001b) and efficiency (Schwarz *et al*., 2003) of siRNA action, and it seems likely that the design of effective siRNAs will soon become a routine operation. Several siRNA supply companies now offer extremely useful on-line siRNA design utilities, some of which also include automatic screening of the nonredundant UniGene database to filter out nonspecific sequences (**http://www.dharmacon.com**).

A second key advantage of siRNAs is their high target specificity. Although it is becoming clear that siRNAs have a range of off-target effects on signaling pathways and gene expression (Sledz *et al*., 2003; Persengiev *et al*., 2004), microarray analysis of gene expression suggests that siRNAs are highly specific tools if their design and delivery are optimized (Semizarov *et al*., 2003). Most potential problems can be addressed by the inclusion of two important experimental controls. First, experiments should always include controls without siRNA, and with targetless siRNAs – this allows for any general effects of siRNAs to be excluded. Second, all observations require confirmation through the use of at least two siRNAs directed to different sites on the target mRNA – this dramatically reduces the possibility that observations are due to effects outside of the intended target. As long as these simple precautions are followed, siRNAs appear to be a robust and highly specific experimental tool.

The third important benefit of siRNAs is their ease of delivery. The small size of siRNAs and the potential for RISC to degrade multiple target mRNA molecules each contribute to this. Because they act in the cytosol, siRNAs have a direct advantage over antisense oligonucleotides in that they only have to cross the plasma membrane to reach their site of action. A number of lipid-based transfer protocols have been developed specifically for siRNA delivery and these have been used successfully on a wide range of primary and cultured cell lines. In our experience, a rough rule of thumb is that cell types that can be transfected with plasmids to at least 25% efficiency can be transfected with siRNAs to 100% efficiency. siRNAs are surprisingly stable in cell culture, with a half-life of around 2–5 days. This lifetime can be increased further through chemical modification of the oligonucleotides (**http://www.dharmacon.com**). Nevertheless, there are still situations where longer-term availability of siRNA is required. Agami and coworkers devised a vector-based system where siRNAs are encoded as small hairpin sequences (shRNA), transcribed from an RNA polymerase III promoter, allowing for long-term gene silencing in cells (Brummelkamp *et al*., 2002a). Equivalent retroviral systems allow for high efficiency of delivery and stable integration into the host genome (Brummelkamp *et al*., 2002b). These varied and efficient delivery systems have important implications for the potential clinical use of siRNA technology; however, for most research scientists, the most exciting recent advance has been the demonstration of stable germline transmission of virally encoded shRNA in a mouse line (Carmell *et al*., 2003). Compared to conventional techniques for targeting of mouse genes through homologous recombination, this is a rapid and straightforward route to achieve gene silencing in whole animals. Perhaps most significantly, it is an enabling technology that makes whole animal studies of gene function feasible for a much larger section of the scientific community.

4. Strategies and screens

Scientists are still coming to terms with the new experimental freedoms that siRNA allows. Perhaps the most significant of these is the feasibility of genome-wide screens in organisms that have not previously been accessible to these techniques.

Schultz and coworkers have recently constructed an siRNA library representing 8000 human genes in a novel plasmid expression system that transcribes the two RNA strands from opposed promoters. Having transfected this arrayed library into cultured mammalian cells, the authors performed an assay for TNFα-induced activation of the transcription factor NF-κB and identified several novel members of this signaling pathway (Zheng *et al*., 2004). In an alternative approach, Mousses and colleagues have perfected microarrays of oligonucleotide siRNAs in a transfection matrix that can be overlaid with monolayers of cultured mammalian cells (Mousses *et al*., 2003). It seems that it will soon be possible to carry out genome-wide screens in cultured mammalian cells for any process that can be quantified on a cellular basis. An example of this approach in a genetically tractable organism has recently been published by Perrimon and coworkers. They used RNA interference with dsRNAs to target 994 *Drosophila* genes and scored the morphology of cells grown in culture, allowing them to identify 160 genes that contribute to cell shape (Kiger *et al*., 2003). Although this work involved *Drosophila* cells and long dsRNAs, it could just as easily have been applied on a larger scale to cultured mammalian cells using siRNAs. The recent advances in high-throughput cell imaging and semi-automated image analysis (Price *et al*., 2002) suggest that such scaling is a practical proposition.

Genome-wide screening experiments fall outside of the day-to-day business of most laboratories; however, siRNA allows for other equally powerful approaches to the analysis of gene function that are easily accessible by most researchers. One generalized situation that deserves highlighting is the analysis of branching pathways. Transcription factors often initiate complex profiles of gene expression; however, DNA microarrays now allow relatively straightforward analysis of expression patterns across whole genomes. By combining siRNA silencing of specific transcription factors with gene profiling, it should be possible to map the gene targets of mammalian transcription factors, and so begin to unravel the complexities of transcriptional regulation – one of the key goals of postgenomic research. Certainly, similar approaches in *C. elegans* suggest that this approach is feasible (Murphy *et al*., 2003). A comparable problem is that of mapping the targets of protein kinases. The human genome contains over 500 protein kinases and approximately 30% of cellular proteins are phosphorylated. Recent advances in the identification of phosphoproteins by solid-phase capture techniques and tandem mass spectrometry has made possible the analysis of complex mixtures of phosphoproteins such as cell lysates (Kalume *et al*., 2003). By combining siRNA silencing of protein kinases with differential analysis of target protein phosphorylation it would seem that we can begin to unravel the tangled networks of protein phosphorylation that constitute so much of cellular signaling.

5. Conclusions

siRNAs combine high specificity with ease of use to make them powerful tools in the assignment of gene function. Most of us are still inwardly digesting the experimental freedoms afforded by these new reagents, and we are in a period of ingenious and imaginative development of siRNA applications. Perhaps the

most exciting aspect of these emerging technologies is that they are widely accessible, allowing the community as a whole to participate in the coming decade of postgenomic research.

Introductory Review

Posttranslational modification of proteins

Martin R. Larsen and Ole N. Jensen
University of Southern Denmark, Odense, Denmark

1. Introduction

Basic biochemistry courses teach that proteins consist of linear chains of amino acid residues, which encode their three-dimensional structure and biological function. Less emphasis is put on the fate and regulation of proteins once they have been synthesized and released from ribosomes. Exceptions include glycogeneogenic enzymes, for example, glycogen phosphorylase, which is regulated by phosphorylation/dephosphorylation as a function of the energy status of the cell, and blood clotting factors such as fibrinogen, which is activated by proteolytic cleavage as a response to injury.

All cells and tissues rely on proper localization and regulation of proteins in order to maintain integrity and biological function and to be able to respond to external stimulation: How do proteins know where to go in the cell and when to perform their duties? For example, how do proteins help propagate rapid signals from the eye lens to the brain and in turn respond by activation of certain muscles in our arms or legs to perform a desired action? The answer to these questions is that proteins are transiently or permanently modified by other proteins/enzymes in a process referred to as posttranslational modification. Posttranslational modifications may encompass covalent attachment (or removal) of chemical moieties, for example, addition of phosphate groups (*see* Article 63, **Protein phosphorylation analysis by mass spectrometry**, Volume 6) or carbohydrate groups (*see* Article 62, **Glycosylation**, Volume 6, Article 64, **Structure/function of *N*-glycans**, Volume 6, and Article 69, **Glycosylation in bacteria: that, what, how, why, now what?**, Volume 6), which provides the cue for the protein to change its conformation and become active or to target the protein to a particular cellular compartment where it may fulfill its function. Yet other types of posttranslational modifications such as ubiquitination destine proteins for degradation. Thus, at any given time, a given protein species may exist in several different forms each of which may have different localization, activity, and function. A list of common protein modifications and their function is outlined in Table 1.

Mass spectrometry (MS), a technique widely used for molecular mass determination of peptides and proteins, is ideally suited to the study of posttranslational

Table 1 Some commonly encountered posttranslational modifications of proteins

PTM type	ΔMass (Da)	Stability	Function and notes
Phosphorylation			Reversible, activation/inactivation of enzyme activity, modulation of molecular interactions, signaling
– pTyr	+80	+++	
– pSer, pThr		+/++	
Acetylation	+42	+++	Protein stability, protection of N-terminus. Regulation of protein–DNA interactions (Histones)
Methylation	+14	+++	Gene regulation (Histones)
Acylation, fatty acid modification			Cellular localization and targeting signals, membrane tethering, mediator of protein–protein interactions
– farnesyl	+204	+++	
– myristoyl	+210	+++	
– palmitoyl	+238	+/++	
– etc.			
Glycosylation			
– N-linked	>1000	+/++	Excreted proteins, cell–cell recognition/signaling
– O-linked	162	+/++	*O*-GlcNAc, reversible, regulatory functions
GPI-anchor	>1000	++	Glycosylphosphatidylinositol (GPI)-anchor, membrane tethering of enzymes and receptors
Disulfide bond formation	−2	++	Intra- and intermolecular cross-link, protein stability
Deamidation	+1	+++	Probably a regulator of protein-ligand and protein–protein interactions, also a common chemical artifact
Pyroglutamic acid	−17	+++	Protein stability, blocked N-terminus
Ubiquitination	>1000	+/++	Destruction signal
Nitration of Tyr	+45	+/++	Oxidative damage during inflammation

For a comprehensive list of protein modifications and the corresponding Δmass values, visit DeltaMass at **http://www.abrf.org/index.cfm/dm.home**.

modifications. The basic premise is that the addition of chemical moieties to proteins will lead to an increase in protein molecular mass, which can be measured by MS. In reality, proteins are usually digested with proteolytic enzymes to generate peptides, which are more amendable to MS analysis. In this case, the challenge is to retrieve, identify, and characterize the peptides that carry the modified amino acid residues (Figure 1). Electrospray ionization (ESI) MS (Fenn *et al*., 1989) and matrix-assisted laser desorption/ionization (MALDI) MS (Karas and Hillenkamp, 1988) are used in such studies to determine posttranslational modifications, including tandem mass spectrometry (MS/MS) for sequencing of the modified peptides (Mann and Jensen, 2003; Jensen, 2004).

The aim of this introductory review is to describe protein phosphorylation (*see* Article 63, **Protein phosphorylation analysis by mass spectrometry**,

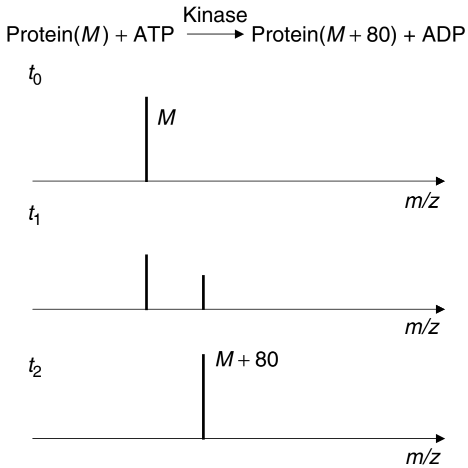

Figure 1 Monitoring posttranslational modification of protein by mass spectrometry. A polypeptide of molecular weight M is incubated with ATP and a protein kinase and aliquots of the sample are analyzed by mass spectrometry at three timepoints. Modification of the protein is evident by observation of an increase in protein molecular weight of 80 Da, corresponding to addition of one phosphate group

Volume 6 and Article 73, **Protein phosphorylation analysis – a primer**, Volume 6) and protein processing (*see* Article 67, **Posttranslational cleavage of cell-surface receptors**, Volume 6). We will outline techniques to investigate these posttranslational modifications by mass spectrometry and complementary biochemical techniques.

2. Protein phosphorylation

Protein phosphorylation is the covalent addition of a phosphate group to one or more amino acid residues within a protein. Each phosphate group adds 80 Da to the molecular mass of the protein or the proteolytically derived peptides and is the basis for MS-based detection techniques. The phosphorylation reaction is catalyzed by protein kinases, which usually utilize ATP or GTP as the phosphate donor. In eukaryote cells, serine, threonine, or tyrosine residues are the substrate sites located within kinase recognition sequence motifs in proteins. For example, protein kinase A recognizes the consensus sequence (R/K)(R/K)x(S/T), that is, a dibasic site followed by any amino acid residue followed by the acceptor serine or threonine residue, such as the motif RRQSLA in human Engrailed-2 protein (Hjerrild *et al*., 2004). Thus, computational sequence analysis can be used to predict putative phosphorylation sites in proteins by a range of well-characterized protein kinases (Blom *et al*., 2004; Hjerrild *et al*., 2004). The human genome contains on the order of 500 genes that encode protein kinases, illustrating the importance of this class of enzyme (Manning *et al*., 2002).

Receptor tyrosine kinases (RTKs) include the insulin receptor, epidermal growth factor receptor (EGFr) and the platelet-derived growth factor receptor (PDGFr),

which play important roles in cellular development and differentiation. Whereas the occurrence of phosphotyrosine is less abundant than phosphoserine and phosphothreonine in mammalian cells, the signaling pathways propagated by RTKs and tyrosine phosphorylation have been relatively well described during the last decade because good reagents are available for their analysis. These include specific inhibitors of RTKs and their downstream targets and anti-phosphotyrosine antibodies for western blotting and immunoprecipitation of phosphotyrosine proteins. Several successful proteomics approaches for studying cell signaling are based on anti-phosphotyrosine antibodies for the recovery of phosphoprotein signaling complexes for subsequent identification by MS (Blagoev *et al*., 2003; Salomon *et al*., 2003; Pandey *et al*., 2000).

Phosphoproteins are substrates for endogenous phosphoprotein phosphatases that remove phosphate groups. When purifying phosphoproteins from cells and tissues it is therefore important to include phosphatase inhibitors, for example, Calyculin A. Most phosphatases recognize specific phosphorylated residues and consensus sequence sites within proteins. However, some phosphatases are nonspecific and will efficiently remove a majority of phosphate on proteins and peptides, for example, alkaline phosphatase and calf intestinal phosphatase.

Purified or recombinant protein kinases and phosphoprotein phosphatases are very useful in MS-based in vitro protein phosphorylation assays, as the addition or removal of phosphate groups leads to a mass increase or decrease of 80 Da (HPO3) or multiples thereof, which is easily monitored by MS (Stensballe *et al*., 2001; Larsen *et al*., 2001b; Qin and Chait, 1997).

Phosphorylation changes the physiochemical properties of proteins as the addition of a phosphate group to an amino acid leads to a lowering of the pK_a value. Phosphorylated amino acids may reduce the cleavage efficiency of proteases, leading to a low yield of phosphopeptide for MS analysis. Furthermore, the lower pK_a value of phosphopeptides relative to unmodified peptides often results in differential detection of phosphopeptide, particularly in MALDI MS. Several methods for enhancing phosphopeptide signals have been reported, including the use of matrix additives in MALDI MS (Asara and Allison, 1999) and immobilized metal affinity chromatography (IMAC) (Neville *et al*., 1997; Figeys *et al*., 1998; Cao and Stults, 1999; Posewitz and Tempst, 1999; Stensballe *et al*., 2001), graphite columns (Larsen *et al*., 2004; Chin and Papac, 1999; Vacratsis *et al*., 2002) and antibodies (Sickmann and Meyer, 2001) for enrichment of phosphopeptides prior to MS analysis. Such methods improve the probability of MS-based detection of phosphorylated peptides in complex mixtures.

3. Phosphopeptide analysis by tandem mass spectrometry

Tandem mass spectrometry is utilized for phosphopeptide detection and sequencing in several different ways. The most commonly used approach is the product ion-scanning mode (*see* Article 18, **Techniques for ion dissociation (fragmentation) and scanning in MS/MS**, Volume 5) in which a phosphopeptide candidate is sequenced by MS/MS to determine which amino acid residue is phosphorylated. This is a very efficient approach, which relies on “picking” the right ion for

sequencing. In those cases in which no phosphopeptide candidates are readily called, then the MS/MS precursor ion-scanning method may reveal the phosphopeptides via selective detection of diagnostic fragment ions, such as *m/z* 216 for phosphotyrosine (Carr *et al*., 1996; Neubauer and Mann, 1999; Steen *et al*., 2001). MS/MS neutral loss scanning (*see* Article 18, **Techniques for ion dissociation (fragmentation) and scanning in MS/MS**, Volume 5) is yet another method that relies on the gas-phase elimination of phosphoric acid (H3PO4, $m = 98$) from phosphoserine- and phosphothreonine-containing peptides (Bateman *et al*., 2002; Schroeder *et al*., 2004).

Whereas most phosphoprotein determinations have been performed by ESI MS/MS, the advent of sensitive and efficient MALDI MS/MS instruments has revived the interest in using this approach for phosphoprotein analysis. Several improvements have been reported, including optimized sample preparation techniques (Kjellstrom and Jensen, 2004; Larsen *et al*., 2004; Stensballe and Jensen, 2004) and use of various types of MALDI tandem mass spectrometers (Bennett *et al*., 2002; Medzihradszky *et al*., 2000; Krutchinsky *et al*., 2001).

Owing to the importance of protein phosphorylation in many biological processes, the systematic determination of phosphoproteins combined with the assignment and quantitation of phosphorylation sites, known as phosphoproteomics, is receiving much attention. Methods for enrichment of phosphoproteins from cell lysates are used in combination with multidimensional chromatography (*see* Article 13, **Multidimensional liquid chromatography tandem mass spectrometry for biological discovery**, Volume 5) and mass spectrometry in large-scale studies aimed at elucidating molecular mechanisms of signal transduction in cellular development, differentiation, and defense. Antibodies specific for phosphoproteins, for example, anti-phosphotyrosine antibodies and anti-PKA substrate antibodies have proven very useful in this endeavor (Pandey *et al*., 2000; Gronborg *et al*., 2002; Salomon *et al*., 2003). Similarly, methods for enrichment of phosphopeptides by IMAC have been extensively used in large-scale phosphoproteomics (Ficarro *et al*., 2003; Brill *et al*., 2004; Nuhse *et al*., 2003). The final stage of phosphoproteomics analysis is tandem mass spectrometry followed by data analysis and interpretation. Quantitative methods based on stable isotope labeling (*see* Article 23, **ICAT and other labeling strategies for semiquantitative LC-based expression profiling**, Volume 5) enable relative quantitation of protein expression and also determination of changes in protein phosphorylation (Mann *et al*., 2002).

4. Protein processing and truncation

Proteolytic processing is a commonly observed posttranslational modification. Signal peptides, which are used to target and localize proteins to different compartments in the cell, are removed during the maturation of the protein. The proteolytic processing of the polypeptide chain is very specific, meaning that the cleavage is taking place at a given amino acid motif. A combination of unspecific and specific processing can be observed during or after changes in the environment, for example, due to cell aging (Ling *et al*., 2003) or osmotic stress (Larsen *et al*.,

2001a). Identifying the exact sites of processing of proteins in the cell is often required in order to elucidate the biological significance of the processing. Several tools for prediction of signal peptides and secretion signals of proteins are available (**www.cbs.dtu.dk**).

The first step in the characterization of proteolytically processed proteins is the efficient detection of the corresponding protein products. Detection of proteolytic processing in proteomics is often performed using two-dimensional gel electrophoresis (*see* Article 22, **Two-dimensional gel electrophoresis**, Volume 5 and Article 29, **Two-dimensional gel electrophoresis (2-DE)**, Volume 5), since processed proteins can be efficiently detected on the basis of migration changes brought about by their reduced size. Depending on the specificity of the processing of the protein, it will migrate into a single spot (specific processing) or give rise to a smear on the gel (unspecific processing) on the 2D gel. Non-gel-based proteomics methods, which rely on the detection of individual tryptic peptides rather than measurement of the intact, processed polypeptides, are not well suited for the study of proteolytically processed proteins because of the difficulty in capturing and defining the N- and C-terminal peptides.

Once isolated, the proteolytically processed protein can be characterized using mass spectrometry in order to locate the exact site for processing, that is, the site of proteolytic cleavage. The most frequently used methods for localizing the exact site is by differential peptide mass mapping using proteolytic enzymes with different cleavage specificities, for example, trypsin and endoproteinase Asp-N (Larsen *et al*., 2001a). Successful analysis relies on the detection of the terminal peptide(s) of the processed protein. Peptides that cannot be immediately mapped to the protein sequence or differ from the peptide mass map of the mature protein are sequenced by tandem mass spectrometry, as they may be derived from the processed termini of the polypeptide. Selective enrichment of the C-terminal peptide by anhydrotrypsin chromatography (ATC), an affinity chromatography method that selectively adsorbs peptides with Arg, Lys, or AECys (*S*-aminoethyl cysteine) residues at the C-terminus under weak acidic conditions, has been demonstrated (e.g., Kumazaki *et al*., 1987).

In a recent study of stress-induced changes in protein expression in *Saccharomyces cerevisiae*, a total of 10 protein spots on a silver-stained 2D gel were identified to represent C- and/or N-terminal processed forms of enolase 2 (Larsen *et al*., 2001a). The C-terminal peptides were identified by mass spectrometry analysis of the peptides derived by in-gel digestion of the proteins in a buffer containing $H_2{}^{16}O$ and $H_2{}^{18}O$ in the proportion 1:1. This results in incorporation of $^{16}O/^{18}O$ (1:1) in all newly generated carboxy termini except the original C-terminal peptide, resulting in a split signal separated by 2 Da for "internal" peptides. Thus, the original C-terminal peptide will exhibit a single peptide ion signal, whereas all other peptides produce a split signal in the mass spectrum.

Presently, the detection of N-terminal peptides is complicated by the reactivity of the N-terminal amino group, which is very similar to the reactivity of the lysine amino group, resulting in no efficient chemistry to tag or label the N-terminal peptide.

5. Conclusions

The elucidation of posttranslational modification of proteins is a prerequisite for understanding the molecular details of living organisms, from bacteria to plants and mammals. The ability to detect and monitor posttranslational modifications of proteins by mass spectrometry and other analytical methods is already providing exciting insights into key regulatory events in cells and organisms, in health and in disease.

Introductory Review

Glycosylation

Richard D. Cummings
University of Oklahoma Health Sciences Center, Oklahoma City, OK, USA

1. Definition of glycosylation

Glycosylation is the enzymatic process of adding sugars in glycosidic linkages to other molecules to generate glycoconjugates or complex carbohydrates, which are defined as molecules that have covalently attached sugars. The process of glycosylation generates all the classes of glycoconjugates, which include glycoproteins, glycosylphosphoinositol (GPI)-anchored glycoproteins, glycolipids, glycosaminoglycans and proteoglycans, peptidoglycans, lipopolysaccharides, free oligosaccharides and polysaccharides, and modified drugs and toxins (Hakomori, 2000; Lis and Sharon, 1993; Power and Jennings, 2003; Rademacher *et al*., 1988; Raetz and Whitfield, 2002; Reiter, 2002; Samuel and Reeves, 2003; Scheible and Pauly, 2004; Spiro, 2002; Upreti *et al*., 2003; Varki, 1993; Wilson, 2002; Zachara and Hart, 2004; Zitzmann *et al*., 2000). Even nucleic acids are a kind of glycoconjugate, since they contain monosaccharide residues, although they are not synthesized by the typical process of glycosylation. Glycoconjugates are found in abundance in higher animals and plants, but most organisms, including all bacteria and most viruses, contain one or more glycoconjugates and thus directly or indirectly carry out glycosylation. Examples of some glycoconjugates in mammalian cells produced by the complex processes of glycosylation are shown in Figure 1. There is also a nonenzymatic mechanism termed *glycation* where sugars chemically react with an amino acid side chain in proteins to generate a covalent attachment of a monosaccharide, but this process is distinguishable from glycosylation (Kikuchi *et al*., 2003).

2. Monosaccharides in glycoconjugates

Mammalian glycoconjugates are built from 10 basic building blocks or sugar precursors (Figure 1), which include the 6-carbon sugars termed hexoses (Glucose – Glc, Galactose – Gal, Mannose – Man, and Fucose – Fuc), the 6-carbon hexosamines (*N*-acetylglucosamine – GlcNAc and *N*-acetylgalactosamine – GalNAc), the 9-carbon Sialic acids (Sia, including *N*-acetylneuraminic acid – NeuAc and *N*-glycolylneuraminic acid – NeuGc), the 6-carbon hexuronic acids (Glucuronic acid – GlcA and Iduronic acid – IdA), and the 5-carbon

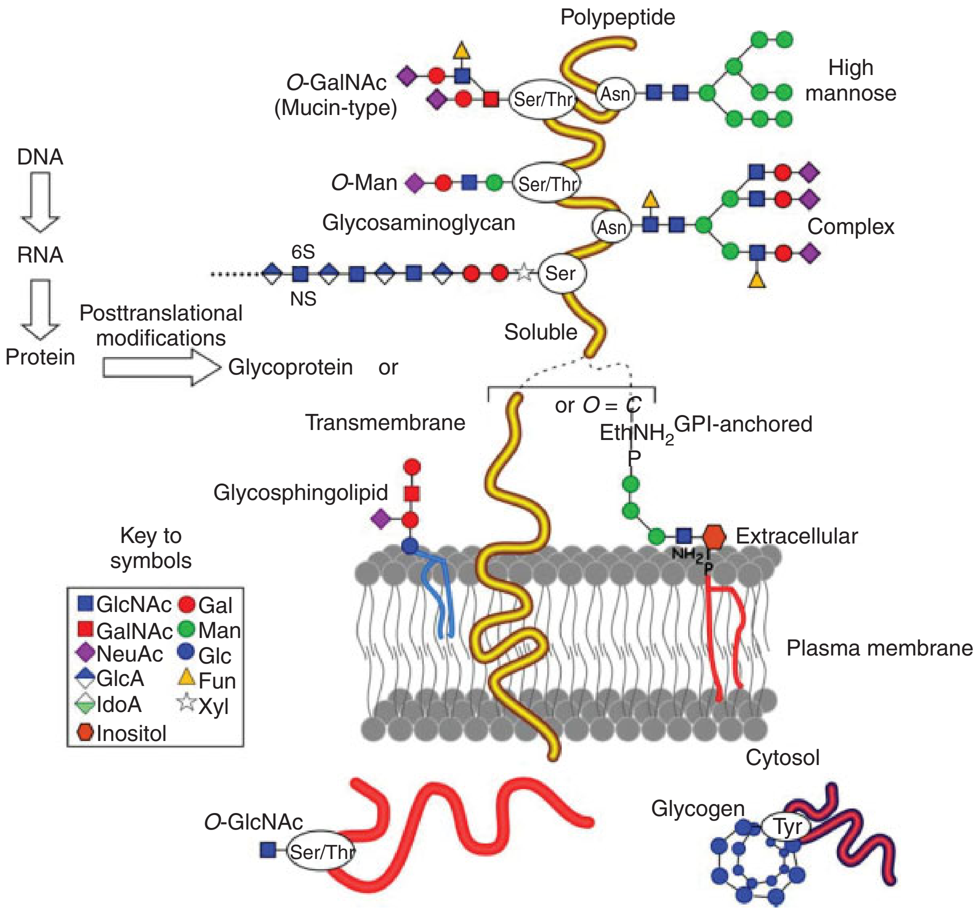

Figure 1 Glycosylation generates the greatest diversity of macromolecules and the largest class of posttranslational modifications of proteins. Examples of composite glycoproteins are shown in the secretions, plasma membrane, and cytoplasm of a mammalian cell, along with glycosphingolipid in the membrane. Monosaccharides are represented by the symbols identified in the key

pentose Xylose (Xyl). Other monosaccharides found in nucleic acids are the 5-carbon pentoses (ribose – Rib and deoxyribose – deoxyRib). While these are major monosaccharides in mammals, other life forms may contain these and/or many different monosaccharides. For example, sialic acids are found in all mammals, but not in all animals and plants. Plant glycoconjugates often contain sugars not found in animals, such as the 5-carbon sugar arabinose (Ara), and the 6-carbon sugars rhamnose (Rha) and fructose (Fruc). Bacteria express many unusual sugars not commonly found in mammalian glycoconjugates, such as 7-carbon sugars termed heptoses, an 8-carbon sugar 2-keto-3-deoxyoctonoic acid (KDO), and a 9-carbon sugar *N*-acetylmuramic acid (MurNAc). Altogether, well over a hundred different monosaccharides have been identified in various glycoconjugates made by different organisms.

3. Structures of glycoconjugates

The monosaccharides in glycosylated molecules are usually linked together within oligosaccharides, which have from 2 to approximately 20 sugar residues, or polysaccharides, which contain more than 20 sugar residues in a chain (Taylor and Drickamer, 2003; Varki *et al*., 1999) (Figure 1) (*see* Article 76, **Analysis of N- and O-linked glycans of glycoproteins**, Volume 6). These oligosaccharides and polysaccharides are generally now referred to as "glycans". Glycan structures are directional. The "reducing end" has the reducing terminus (i.e., the chemical reducing activity of an aldehyde or ketone) when the glycan is free. Most sugars in glycoconjugates are aldoses, that is, sugars with an aldehyde group at carbon 1, such as Glc, but some glycoconjugates also contain sugars that are ketoses, that is, sugars with a keto group at carbon 2, such as Fruc. Glycans are usually linked through their reducing end to another molecule. The opposite end of the glycan is termed the "nonreducing end". In regard to glycoproteins, there is enormous diversity in the ways they can be glycosylated. Some glycoproteins contain a single sugar residue or a single glycan linked to an amino acid. Some glycoproteins, such as mucins, contain thousands of glycans each linked to specific amino acids within the mucin. Over two dozen linkages of sugars to proteins have been identified so far. The linkage of one sugar to another or to a non-carbohydrate component (termed an aglycone) is typically an O-glycosidic linkage (or bond) characterized by −C−O−C−that is formed by the double condensation of an aldehyde with alcohols. The O-glycosidic linkage is known as an acetal. In typical glycans, the monosaccharide residues occur as 6-member rings known as a pyranose, but some glycans have monosaccharides that occur as 5-member rings known as a furanose. The linkage between each sugar is through an anomeric carbon that is optically active and in either alpha or beta anomeric linkage to the other component. The carbon at the reducing end of a sugar residue is the anomeric carbon (usually carbon 1 for aldoses and carbon 2 for ketoses). Each monosaccharide occurs in nature as either an optically active D or L enantiomer (an enantiomer is a molecule that is a mirror image isomer of another molecule). The presence of enantiomers is not random because one is usually preferred over the other in biology. For example, all glucose residues in animals are D enantiomers (D-Glc), and all fucose residues appear as L enantiomers (L-Fuc). Enzymes that recognize a particular enantiomer (e.g., D-Glc or D-Gal) usually do not recognize the L-form of that sugar. Consider as an example the disaccharide sequence D-Gal-beta-1-4-D-Glc (abbreviated Galβ1→4Glc), which can be read as showing that D-Gal is β-linked from its carbon 1 through the hydroxyl group at carbon 4 of D-Glc. The D-Glc residue is at the reducing end and the Gal residue is at the nonreducing end. This is the structure of lactose, which is the common sugar found in milk. A conjugate in nature containing this sugar is the glycolipid lactosylceramide, which has the structure Galβ1→4Glcβ1→ceramide and is one of the simplest glycolipids found in animals. Linkages of sugars to each other can produce di-, tri-, tetra-, penta-, hexasaccharides, and so forth. But unlike other building blocks for other biological polymers, such as nucleic acids and proteins, monosaccharides within glycans may be branched. This branching is a key feature of many glycans and allows a tremendous diversity of structures to be generated from a relatively small number

of building blocks. Thus, many glycans may have the same size and composition, but because of differences in the way they are branched, or the anomeric linkage between them, glycoconjugates of the same monosaccharide composition can vary enormously in structure. It has been calculated that six monosaccharides can be theoretically linked in different ways to make as many as 1×10^{12} different hexasaccharides (Laine, 1994). By contrast, six amino acids can be theoretically linked in different ways to make only 6.4×10^{7} different hexapeptides. Sugars can be linked to amino acids in proteins in multiple ways, but the most common are O-glycosidic linkages –C–O–C–and *N*-glycosidic linkages –C–N–involving amide linkages of sugar to an amino acid. In animal cell glycoproteins, the *N*-glycans (also termed Asn-linked oligosaccharides) are attached to the amino acids asparagine (Asn) as *N*-glycosides such as *R*-GlcNAcβ1→Asn (Figure 1). *O*-glycans are usually linked as *O*-glycosides to the hydroxylated amino acids serine (Ser) and threonine (Thr), hydrolysine, hydroxyproline, and tyrosine (Tyr) (*see* Article 65, **Structure/function of *O*-glycans**, Volume 6). There are also many less common forms of attaching glycans to proteins, such as C-mannosylation of tryptophan, which involves a direct carbon–carbon (–C–C–) bond between the sugar and an amino acid bond rather than a glycosidic bond. Linkages of sugars to lipids are often through a glycosidic bond to a lipid alcohol group, as seen above for lactosylceramide or through a phosphoester linkage. Phosphoester linkages between sugars are also found within some polysaccharides, such as the protozoan parasite-derived lipophosphoglycans and in bacterial teichoic acids, which are polymers containing phosphate groups joining glycerol or ribitol (a reduced form of ribose).

4. Occurrence of glycoconjugates

Glycoconjugates are found on the surfaces of cells as either intrinsic or extrinsic membrane components, but they also occur within cells (cytoplasmic localization and in organelles), and in cell secretions. Glycoconjugates are the basis of the human ABO blood group antigens, and many other less-well-publicized blood group antigens, such as the Lewis antigens and P antigens (Hakomori, 1999) that occur on cell surface and secreted glycoconjugates. It has been estimated that in mammals, a majority of the gene-encoded proteins are glycosylated (Apweiler *et al*., 1999). Glycosylation is considered to be the most common, and complex, type of "posttranslational modification" of proteins. While the number of human genes is now estimated to be between 20 000–25 000, the number of differently glycosylated proteins (glycoforms) may be in the many millions. This is because different cell types often glycosylate the same protein differently, and can differentially glycosylate amino acids within a single glycoprotein. Differences in glycan structures on a single glycoprotein species are sometimes referred to as *microheterogeneity*. The field of study that attempts to define all the structures of all the glycoconjugates is termed glycomics (Drickamer and Taylor, 2002; Sutton-Smith *et al*., 2002). It has analogy to genomics and proteomics, which are the sequences of all genes and definition of all expressed proteins, respectively, in an organism (*see* Article 74, **Glycoproteomics**, Volume 6). Bacteria are covered by a glycoconjugate coat, which is composed of peptidoglycan (a polysaccharide

containing covalently attached amino acids), and lipopolysaccharides, a composite of sugars linked to membrane lipids. Some bacteria also make glycoproteins where sugars are covalently linked amino acids (Schaffer and Messner, 2004), as found in animal glycoproteins, although the glycan structures are different. Each type of bacteria generates different glycan structures; in pathogenic bacteria that infect animals, these glycans are often antigenic. Many antibiotics, such as penicillin and bacitracin, interfere with glycoconjugate assembly in bacteria (*see* Article 69, **Glycosylation in bacteria: that, what, how, why, now what?**, Volume 6). In general, all cells appear to contain abundant amounts of glycosylated molecules on their surfaces and in their secretions.

5. Sites of glycosylation in cells

All of the sugars that a cell needs for glycosylation are synthesized directly within cells from de novo metabolic synthesis or interconversions, but cells can also transport many sugars into their cytoplasm from the outside. Animals, fungi, bacteria, and possibly carnivorous plants can acquire monosaccharides by uptake of monosaccharides released through the degradation of glycoconjugates in food. Glycosylation in animal cells occurs in many different cellular compartments such as the cytosol, the secretory organelles, which include the endoplasmic reticulum and Golgi apparatus, and the plasma membrane (Young, 2004). Glycosylation in bacteria occurs primarily in the outer membrane. Viral glycoproteins are normally synthesized by enzymes produced by the host cell that the virus invades.

6. Process of glycosylation

Higher animals and plants have hundreds of individual genes encoding the enzymes that are involved directly in glycosylation to catalyze the transfer of sugar, for example, transferases (Davies and Henrissat, 2002). There are also hundreds of other genes involved in synthesis and turnover of glycosylation precursors and intermediates, such as the monosaccharides and lipids. There appear to be at least five major classes of enzymes that catalyze glycosylation reactions (Figure 2). The most common class comprises the glycosyltransferases that transfer sugar to an acceptor molecule using sugar nucleotide donors; in most cases sugar addition occurs to the nonreducing end of the glycan, but in some special cases it may occur to the reducing end. Examples of sugar nucleotide donors are uridine-diphospho-glucose (UDP-Glc) and UDP-GlcNAc. Some less common sugar nucleotide donors are guanosine-diphospho-fucose (GDP-Fuc) and cytosine-monophospho-sialic acid (CMP-Sia). Other types of transferases transfer sugar from a lipid-phospho-glycan donor, such as dolichol-phospho-mannose and dolichol-pyrophospho-oligosaccharide to acceptor molecules. The addition of sugar to Asn residues in animal cell glycoproteins occurs by the en bloc addition of a preformed glycan from a dolichol-pyrophospho-oligosaccharide during protein translation (cotranslational modification) in the rough endoplasmic reticulum, coupled by the release of dolichol-pyrophosphate (Yan and Lennarz, 1999) (Figure 2). Such

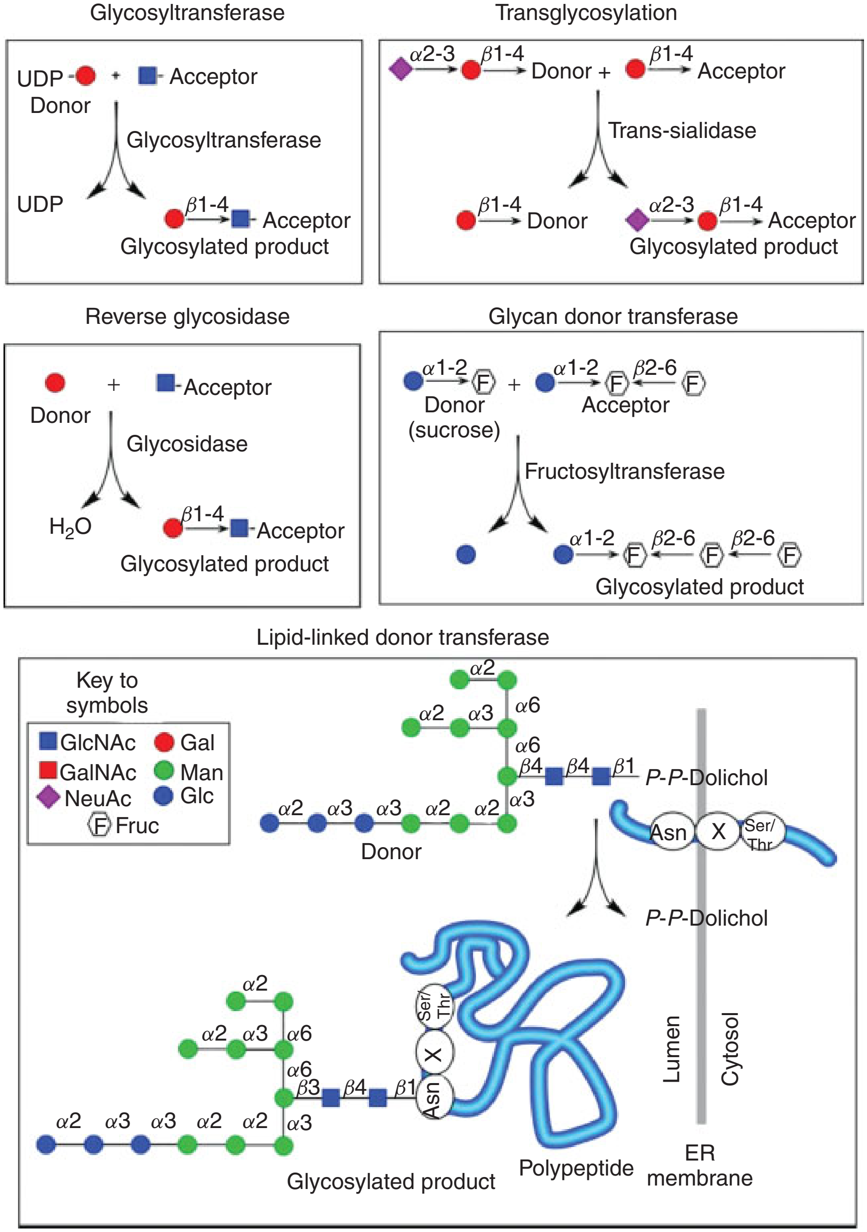

Figure 2 There are several types of glycosylation reactions. Shown are five major pathways in which acceptor molecules are enzymatically glycosylated. Donors for the reactions are shown on the left side within each box and the acceptor and glycosylated product are shown on the right side. Monosaccharides are represented by the symbols identified in the key

glycosylation can be blocked in cells treated with the antibiotic tunicamycin, which blocks the formation of the dolichol-pyrophospho-oligosaccharide donor. Bacteria lipopolysaccharides are also synthesized by the en bloc transfer of preformed lipid-phospho-glycans intermediates to growing polysaccharide chains. The recycling of the lipid-phosphate in this bacterial process is inhibited by the antibiotic bacitracin. Within the Golgi apparatus of eukaryotic cells, other sugars are enzymatically removed and added to glycoproteins in a stepwise fashion through glycan "trimming" and "processing" reactions. Glycoproteins acquire their "mature" structures upon completion of this complex trafficking (Kornfeld and Kornfeld, 1985; *see also* Article 64, **Structure/function of *N*-glycans**, Volume 6). Some organisms use transglycosidases that catalyze sugar addition through a transglycosylation reaction whereby a terminal sugar is enzymatically removed from one glycan and donated to another. Such reactions are used by pathogenic protozoans to coat themselves with sialic acid from host tissues (Pereira-Chioccola and Schenkman, 1999). Interestingly, sugar addition can also occur by the reverse action of glycosidases, which normally remove sugars from a glycoconjugate (Bertozzi and Kiessling, 2001). Finally, in a pathway possibly unique to plants, a disaccharide can also be a donor in the glycosylation of a larger polysaccharide, as is seen for sucrose (a disaccharide of glucose linked to fructose). The enzyme fructosyl transferase transfers Fruc from sucrose to a growing Fruc-containing polysaccharide (fructan), with the release of free Glc (Cairns, 2003).

7. Sizes of glycoconjugates

Glycoconjugates come in all sizes and are among the largest and the smallest polymers in nature (Rademacher *et al*., 1988; Varki *et al*., 1999). Glycogen, the major storage polysaccharide of animals, which is composed of repeating and branched α-linked Glc residues, is actually a glycoprotein, where a glucose residue is linked to the amino acid Tyr to form the glycoprotein glycogenin (Lomako *et al*., 2004). The attached glycogen chain may have a molecular size over 10 million Da. Plants might have a related protein to which starch is linked. Starch is also a long branched polymer of α-linked Glc residues. The alpha linkages between Glc residues in glycogen and starch help them to structurally fold in a compact form and conserve space. Plants also synthesize probably one of the largest glycosylated molecules, which is cellulose, a linear polymer of β-linked Glc residues, which may have a size of many millions of daltons. The beta linkage of the Glc residues in cellulose causes it to be more linear and unable to fold like glycogen or starch. Crustaceans generate chitin, which is a linear polysaccharide of GlcNAc residues in beta linkage to each other and may have a size greater than 10 million Da. Some glycosaminoglycans in animals can also have enormous sizes. Hyaluronic acid, a polysaccharide of alternating GlcNAc and GlcA residues, has a size greater than 5 million Da. Animal heparin is an anticoagulant polysaccharide composed of alternating sulfated GlcNAc and GlcA or IdA residues with a size up to 40 000 Da. In animals, glycoproteins come in all sizes; some are extremely large and some are very small. For example, a human mucin termed MUC4 that is present in mucous secretions is a membrane-associated glycoproteins over 2 µm

in length, with a polypeptide backbone of over 900 000 Da (>8000 amino acids) that is heavily glycosylated on multiple threonine and serine residues (Lamblin *et al*., 2001). The actual molecular weight of such a mucin approaches several million daltons (*see* Article 70, ***O*-glycan processing**, Volume 6). One of the smallest glycoproteins in humans is CD59, which is the principal cellular inhibitor of the C5b-9 membrane attack complex (MAC) of human complement (Smith, 2004). CD59 is a GPI-anchored membrane glycoprotein with only 77 amino acids in the mature protein (*see* Article 66, **GPI anchors**, Volume 6 and Article 77, **Glycosylphosphatidylinositol anchors – a structural perspective**, Volume 6). It has a glycan in amide linkage to an asparagine residue at position 18 and the C-terminal amino acid is linked to a GPI-anchor in the membrane. The glycan attached to that asparagine residue can account for 30–50% of the total mass of the glycoprotein. Glycolipids also vary greatly in size but they are almost always smaller than glycoproteins (Hakomori, 2000). Typical glycolipids in animal cells range in size from 1000 to 4000 Da. One of the largest polymeric complexes containing sugar in nature is the peptidoglycan on bacteria that is cross-linked, as seen, for example, in mycobacteria (Crick *et al*., 2001), to provide a virtual single molecular net covering that promotes pathogenesis and protects bacteria from osmotic shock.

8. Functions of glycosylation

Glycosylation has many important biological functions. Glycans function as structural components (e.g., glycosaminoglycans and proteoglycans, cellulose, chitin, glycolipids), energy sources (e.g., sucrose, glycogen, starch), and recognition components for carbohydrate-binding proteins (CBPs). Many different glycans are known to be bound by CBPs (also termed lectins) (Sharon and Lis, 2004; Taylor and Drickamer, 2003). As discussed below, defects in glycosylation often result in disease and death. Glycosylation of proteins in the cytosol and nucleus by the addition of a single monosaccharide GlcNAc to Ser or Thr amino acids in proteins can regulate gene expression, protein interactions, and protein turnover (*see* Article 72, **O-linked *N*-acetylglucosamine (*O*-GlcNAc)**, Volume 6). During biosynthesis of glycoproteins in the rough endoplasmic reticulum of animal cells, the addition of glycans to Asn amino acid residues is part of a process of protein folding termed quality control (QC) (Helenius and Aebi, 2004; Parodi, 1999). This QC process is complex and involves a large number of enzymes that modify glycans and proteins that recognize the glycans on newly synthesized glycoproteins. Defects in the QC process regarding glycoproteins are often detrimental to cell survival. Glycoproteins on the surfaces of cells participate in cell–cell adhesion and recognition through binding by CBPs, as is seen for sperm–egg binding essential to fertilization, and in white blood cell (lymphocyte) adhesion and extravasation or movement into tissues and lymph nodes (Lowe, 2002; Lowe and Marth, 2003; Sharon and Lis, 2004). Surface glycoconjugates are involved in a myriad of cell signaling activities, since virtually all proteins on the surfaces of animal cells are glycosylated. Glycoconjugates within the extracellular matrix are essential to tissue integrity and to cell adhesion within the matrix. Many hormones are glycoproteins,

such as erythropoietin, which stimulates red blood cell production. Glycosylation of toxins (xenobiotics) is a part of the mechanism for clearance and detoxification. A typical toxin glycosylation is the addition of GlcA from UDP-GlcA donors in the liver, resulting in enhanced toxin solubility and inhibition of its toxin function. Even common hormones, such as testosterone and estrogen, are glycosylated by the addition of GlcA. Glycoconjugates are also essential nutrient components for cells. Thus, it is understandable that defects in glycosylation are associated with many diseases and disorders.

9. Disorders associated with glycosylation

A large number of human disorders and diseases are caused by defects in glycosylation. From a historical perspective, it has been known for nearly a century that some people have genetic defects resulting in an inability to degrade certain types of glycoconjugates (the process termed catabolism). Such defects are recognized as lysosomal storage diseases (Neufeld, 1991). Many dozens of such disorders are known. Some of the more noteworthy ones are Tay-Sachs disease, caused by a deficiency of β-hexosaminidase resulting in accumulation of an undegraded ganglioside (a glycolipid) GM2 in the brain, Gaucher disease, caused by a deficiency in β-glucocerebrosidase resulting in accumulation of several undegraded glycolipids, and Hurler syndrome, caused by a loss of α-L-iduronidase resulting in the accumulation of undegraded glycosaminoglycans. But in recent years, scientists have shown that many other human genetic disorders result from defects in the ability to glycosylate proteins or generally synthesize correctly glycosylated molecules. Many of these disorders are grouped as Congenital Disorders of Glycosylation (CDGs) (Jaeken, 2004). Because glycoconjugates are important in animal biology and development, these genetic diseases are rather uncommon. Some CDG patients are unable to synthesize sugar nucleotides, the precursors for glycosylation, while others inefficiently add glycans to newly synthesized proteins. But there are many other known defects in glycosylation outside the CDG categories, such as I-cell disease (Kornfeld and Sly, 1985), congenital muscular dystrophy (Endo and Toda, 2003), and defects in glycosaminoglycan biosynthesis (Zak *et al*., 2002). In I-cell disease, patients lack the enzyme that adds GlcNAc-phosphate residues to Man residues on lysosomal hydrolases. Normally, the presence of phosphate on Man residues is required for the correct localization of lysosomal hydrolases in their eventual destination within the lysosome. However, for I-cell patients, lysosomal enzymes are not correctly targeted to lysosomes and the fibroblasts in a patient's body inefficiently degrade a wide variety of glycoconjugates and proteins. In some forms of congenital muscular dystrophy, patients lack an enzyme that adds GlcNAc residues to O-linked mannose residues on glycoproteins, resulting in muscle weakness (*see* Article 71, ***O*-Mannosylation**, Volume 6). Mouse genetics has also shown the requirement for correct glycosylation in animal development (Lowe and Marth, 2003). Mice engineered to lack some glycosyltransferases die as embryos or fail to develop properly postpartum. Tumor cells also appear to express altered

glycoconjugates due to changes in glycosyltransferase and glycoprotein expression (Alper, 2003; Hakomori, 2001; Varki and Varki, 2001). It is now clear that glycosylation of macromolecules is a common and essential biological process.

10. Conclusions

In the past decade, there has been an explosion of interest in glycosylation and the biological functions of glycoconjugates. Each cell type within an animal appears to generate a unique repertoire of glycoconjugate structures, determined in large part by the regulation of the glycosylation machinery. Glycans function as structural components, energy sources, and they also function as recognition components for a large array of carbohydrate-binding proteins. A large number of genes in higher animals regulate glycosylation, and genetic defects in these pathways result in developmental abnormalities and embryonic death.

1. Introduction

One of the most common types of posttranslational protein modifications is protein phosphorylation. In prokaryotes many different amino acid residues including histidine, aspartic acid, glutamic acid, lysine, arginine, and cysteine, residues can be found in their phosphorylated forms, whereas the main targets for phosphorylation in eukaryotes are serine, threonine, and tyrosine residues (Yan *et al*., 1998). It is estimated that about one-third of all proteins in mammalian cells are phosphorylated at any given time and that about 5% of a vertebrate genome encodes for protein kinases and protein phosphatases (Hunter, 1998), underscoring the importance of this type of protein modification. The presence of this large variety of protein kinases and phosphatases permits the use of reversible protein phosphorylation in a vast number of different, highly regulated pathways and functions. The fast reversibility of protein phosphorylation renders it versatile for cell regulation, such as metabolism, cell division, cell differentiation, cell proliferation, and signal transduction, which require "off"- and "on"-states and fast switching between these two states for fully functional regulatory mechanisms.

The exact localization of phosphorylation sites is of pivotal interest when trying to understand detailed mechanisms of cellular regulatory processes. This calls for fast and sensitive methods for the detection and localization of protein phosphorylation. The most sensitive methods for the detection of phosphorylation utilize radioactive phosphorus isotopes such ^{32}P or ^{33}P. In these experiments, radioactive phosphorus isotopes are incorporated in vivo or in vitro into proteins of interest, which are subsequently digested, and phosphopeptide mapping is performed either using two-dimensional thin layer chromatography or liquid chromatography. Autoradiography and/or densitometry can then be used to localize and/or quantitate the labeled spots or fractions (Hunter and Sefton, 1991). Edman-degradation-based approaches can also be used, whereby the release of radioactivity

during one particular cycle from the immobilized peptide can be correlated with the site of phosphorylation (Campbell and Morrice, 2002). However, the in vivo incorporation of the radioactive isotope is not possible in the case of tissue samples and is very inefficient in the case of cell culture due to the presence of endogenous unlabeled adenosinetriphosphate (ATP) such that large amounts of radioactively labeled ATP are required to achieve a degree of in vivo phosphorylation that is sufficient for sensitive detection. Thus, there is a need for other, nonradioactive methods, especially for the analysis of in vivo protein phosphorylation. One commonly followed strategy utilizes generic anti-phosphoserine, -threonine, or -tyrosine antibodies either for profiling and the subsequent comparison of different (cell) states (Godovac-Zimmermann *et al*., 1999). Antibodies can also be used for detailed analyses of phosphorylation sites. This is performed by using site-specific antibodies in contrast to antibodies against global phosphoamino acid residues used for the former type of experiment described. However, the latter approach requires the identification and localization of the phosphorylation site by other means such as mutational scanning or by utilizing radioactivity or nonradioactive methods. The most versatile nonradioactive method is mass spectrometry, and this technology provides unrivaled sensitivity and speed when compared with traditional biochemical methods. This review summarizes the most commonly used mass spectrometry–based approaches for phosphorylation analysis and highlights new developments in the field of phosphoproteomics as of end of 2004.

2. What are the challenges in analyzing protein phosphorylation?

Currently, protein identification by mass spectrometry is a standard technique that can be automated to a large degree by companies and core facilities around the world (*see* Article 31, **MS-based methods for identification of 2-DE-resolved proteins**, Volume 5). This is in contrast to protein phosphorylation analysis (or protein modification analysis in general) which is still far from being routine and/or automated. The main difference between these procedures is that for identification purposes any set of peptides or even one peptide is sufficient for an unambiguous protein identification, whereas for protein phosphorylation analysis, the modified peptide has to be found and analyzed such that for the "complete" protein characterization, close to 100 % sequence coverage is required – and this is not normally achieved because of certain intrinsic limitations: (1) mass spectrometry is most sensitive in a particular *m/z* range such that peptides that are on either extreme ends of the *m/z* scale are inefficiently detected; (2) the cleavage efficiency varies for different proteins and different domains within the proteins, such that some expected peptides are not generated; (3) peptides have different ionization and detection responses, and thus signal intensity can easily vary by orders of magnitude for peptides derived from the same protein (*see* Article 16, **Improvement of sequence coverage in peptide mass fingerprinting**, Volume 5). The latter point is far from being fully understood; however, some preliminary studies showed that the peptide length, number of lysine and glutamic acid residues as well as the propensity to

form α-helices seem to have an effect on the ionization and detection efficiencies of the different peptides (Schirle *et al*., 2004). These general reasons for not observing all peptides are further complicated by other phosphospecific reasons for phosphopeptides being missed during mass spectrometric analysis. These include substoichiometric degrees of phosphorylation and heterogeneous phosphorylation, both of which lead to lower amounts of phosphopeptides of a specific *m/z* as compared to unmodified peptides from the same protein of interest. Furthermore, phosphopeptides tend to have lower ionization/detection efficiencies when analyzed by MALDI mass spectrometry especially when 4-hydroxy-α-cyanocinnamic acid is the matrix used – one of the reasons for this might be that fragmentation of the labile phosphomoiety is induced by in-source decay during the ionization process (*see* Article 11, **Nano-MALDI and Nano-ESI MS**, Volume 5 and Article 14, **Sample preparation for MALDI and electrospray**, Volume 5).

Serine and threonine-phosphorylated peptides cause additional problems during mass spectrometric analyses because of their fragmentation behavior when using collisional activation conditions normally used to obtain sequence-revealing fragment ions. The product-ion spectra of these species are normally dominated by fragment ions resulting from the neutral loss of the phosphomoiety as phosphoric acid (H_3PO_4 corresponding to 98 Da; note that the difference in the mass spectrum is given by n*98/z, n being the number of phosphomoieties on the peptide of interest and z being the charge state of the precursor of interest). Since this loss of phosphoric acid is energetically favored, other sequence/phosphorylation site-revealing fragment ions are often absent (*see* Article 4, **Interpreting tandem mass spectra of peptides**, Volume 5). This is especially relevant in ion trap instruments where a resonant frequency is used for the excitation (*see* Article 9, **Quadrupole ion traps and a new era of evolution**, Volume 5) collisionally induced dissociation (CID) once the predominant fragment ions that lost the phosphoric acid group are formed they are off-resonance with the applied excitation frequency and are no longer excited/fragmented (see Figure 1). This is in contrast to collisional activation in high-pressure multipoles (non-ion trap); here the fragment ion that underwent the neutral loss usually fragments further by additional collisions while traversing the collision cell, such that useful sequence information is often obtained.

Since this neutral-loss ion is normally the first fragment ion formed, the originally phosphorylated residues are converted into dehydroalanine (69 Da) and dehydroaminobutyric acid (83 Da) residues. These residues are indicative of the phosphorylation site and have to be considered during interpretation of the product-ion spectra in order to localize the site of phosphorylation; unfortunately, these residues are often not considered by some of the current protein-identification programs and as such many phosphopeptides may not be identified.

This problem of a predominant loss of the phosphomoiety can be circumvented by using a novel (peptide) fragmentation process called electron capture dissociation (ECD) (Zubarev *et al*., 1998). This process is based on the capture of thermal electrons that induce radical chain reactions resulting in the predominant peptide cleavage at the N–αC bond without fragmenting the most labile side chain modifications including phosphorylation (see e.g., Stensballe *et al*., 2000) such that the site of modification can be easily and unambiguously identified even if a

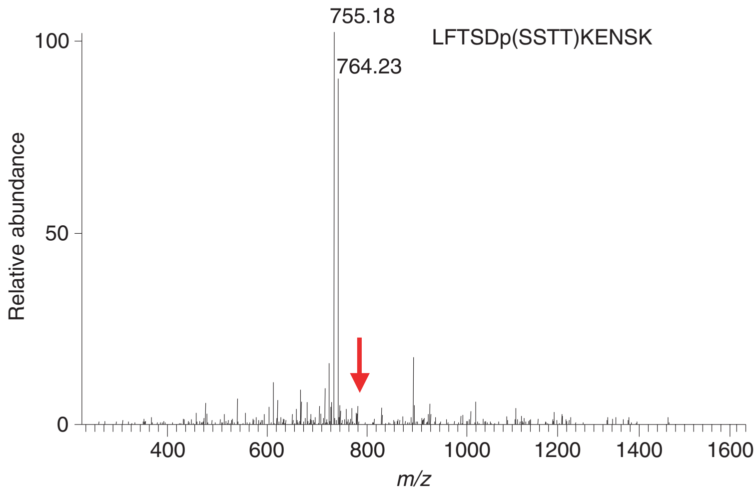

Figure 1 Product ion spectrum of a precursor at *m/z* 813.16 (red arrow) acquired on a quadrupole ion trap mass spectrometer. The predominant neutral loss of 98 Da (H_3PO_4) and 116 Da ($H_3PO_4 + H_2O$) is clearly visible. However, other sequence-revealing fragment ions are only of minor abundance such that it is only possible to identify the peptide but not the exact site of phosphorylation (shown as p(SSTT))

highly phosphorylated species containing numerous serine and threonine residues is fragmented (see e.g., Figure 2).

The disadvantages of this method include (1) the requirement of expensive FT-ICR instruments (*see* Article 5, **FT-ICR**, Volume 5), (2) low efficiency of electron capture and hence low fragmentation yield, and (3) the fact that ECD fragmentation in an LC-compatible timescale is still a challenge. However, preliminary data for

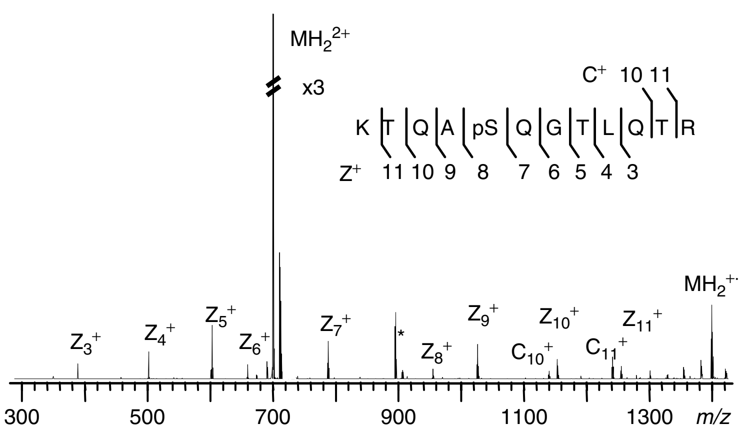

Figure 2 An ECD product ion spectrum of the phosphorylated peptide KTQA(pS)QGTLQTR. In contrast to collision induced activation, no loss of H_3PO_4 (−98 Da) is observed owing to the nature of ECD and instead of B- and Y-type fragment ions, only C- and Z-type fragment ions are generated (Figure courtesy of Dr. Bogdan Budnik, then University of Southern Denmark)

ECD fragmentation in quadrupole ion traps have recently been presented (Silivra *et al*., 2004). In addition, another novel fragmentation approach, Electron Transfer Dissociation (ETD) has been introduced in linear ion traps. ETD utilizes gas-phase reactions between protonated peptides and a basic radical anions, transferring electrons upon collision, thereby inducing ECD-like peptide fragmentations with all its advantages (and also its disadvantage of low fragmentation yields) in a cheaper type of mass spectrometer. This technique shows promise for obtaining intact phosphopeptide fragmentation data in LC/MS compatible timescales (Syka *et al*., 2004).

3. Given the obstacles, how is protein phosphorylation analyzed by mass spectrometry?

3.1. Brute force

The most common means of phosphorylation analysis by mass spectrometry is by using "Brute Force" methods. This approach entails the extensive analysis of the sample of interest by LC/MS prior to exhaustive data mining using database search programs such as MASCOT, Sequest, Sonar, or ProID where mass differences of 80 Da (and multiples thereof) due to (multiple) phosphorylation are considered in database searches. Although such a strategy is valid as a first-pass analysis, the disadvantages are obvious; since only "observed" peptides (conditional on the parameter used for the data dependent MS^2 experiments) are fragmented, the vast majority of the fragmented peptides are unmodified peptides such that the majority of information collected is redundant as the identity of the protein of interest is already known after the first unmodified peptide from any given protein is successfully fragmented and searched against a database. This means that the analysis of phosphopeptides is only a side product of such a brute force strategy and the shortcomings of such an analysis are that (1) phosphopeptides of low abundance are often missed, especially during the analysis of more complex samples and (2) the analysis often only provides insufficient fragmentation information to unambiguously localize the phosphorylation because of poor phosphospecific fragmentation (see above or below). A further complication might be caused by sulfation, another protein modification that gives rise to the same mass increase as phosphorylation but shows a different fragmentation behavior. Although the mass shift of the precursor ion caused by a modification is taken into account by the currently used database search programs, the differing fragmentation patterns are often not considered such that sulfation can easily be mistaken for phosphorylation. It was thought that sulfation only occurred on tyrosine residues of extracellular proteins; however, a recent study provides evidence that serine or threonine residues of intracellular mammalian proteins can also be sulfated (Medzihradszky *et al*., 2004).

In order to avoid all the shortcomings associated with the brute force technique listed above, different approaches are necessary for more efficient phosphorylation analysis. The most commonly used approaches utilize of the selective/specific mass spectrometric detection of phosphorylated species based on (1) their characteristic

fragmentation behavior upon collisionally induced dissociation and/or (2) the selective enrichment of phosphorylated species using affinity purification strategies. Often, combinations of these methods are utilized. Other approaches including chemical derivatization and phosphatase treatment have been described as well.

3.2. Selective detection

As detailed previously, phosphorylated peptides exhibit a characteristic behavior on collisionally induced activation in tandem mass spectrometers: (1) In the negative ion mode (detection of anions, i.e., deprotonated species), PO_3^- is observed as characteristic fragment ion at *m/z* −79. It is highly specific for any type of phosphorylated species, that is, in the case of phosphopeptides and proteins this ion at *m/z* −79 is observed irrespective of whether serine, threonine, or tyrosine is phosphorylated. (2) In the positive ion mode (detection of cations, i.e., protonated species), phosphopeptides tend to lose the phosphomoiety as a neutral phosphoric acid molecule giving a "signature" ion pair in the MS/MS spectrum spaced by a *m/z* of 98/*z* (*z* being the charge state of the precursor) for each phosphomoiety contained in the peptide of interest. A caveat of this signature fragmentation is that this loss is only observed for phosphoserine- and phosphothreonine-containing peptides. Phosphotyrosine-containing peptides give rise to a characteristic fragment ion at *m/z* 216.043, which can be utilized when high resolution, high accuracy tandem mass spectrometers such as quadrupole TOF instruments are employed (*see* Article 10, **Hybrid MS**, Volume 5; Steen *et al*., 2001; Steen *et al*., 2002).

3.3. Precursor ion scanning

Precursor ion scanning allows for the selective detection of only those parent ion species that give rise to the phosphospecific fragment ion upon peptide dissociation. Although precursor ion scanning has a superb specificity and is extremely sensitive such that species of interest hidden in the chemical noise can easily be detected, limitations have been described for precursor of *m/z* −79 and precursor of *m/z* 216.043 experiments (see Figure 3).

In the former case, the deprotonated peptide giving rise to the specific PO_3^- ion is preferentially formed in alkaline solution and requires that the instrument be run in negative ion mode. This prevents the immediate sequencing of the peptide as deprotonated ions normally do not give rise to sequence-revealing fragment ions. The latter phosphotyrosine-specific experiments require a high resolution, high accuracy quadrupole TOF instrument, which does not allow precursor ion scans in a LC-compatible timescale as the second mass analyzer, the TOF tube, cannot be operated in a mass filter mode. Instead, distinct product-ion spectra have to be acquired for each precursor mass prior to computing the intensity of the characteristic reporter ion versus the *m/z* value of the precursor. Use of such an approach requires 30 s or more and this time frame is incompatible with LC/MS experiments that are currently standard.

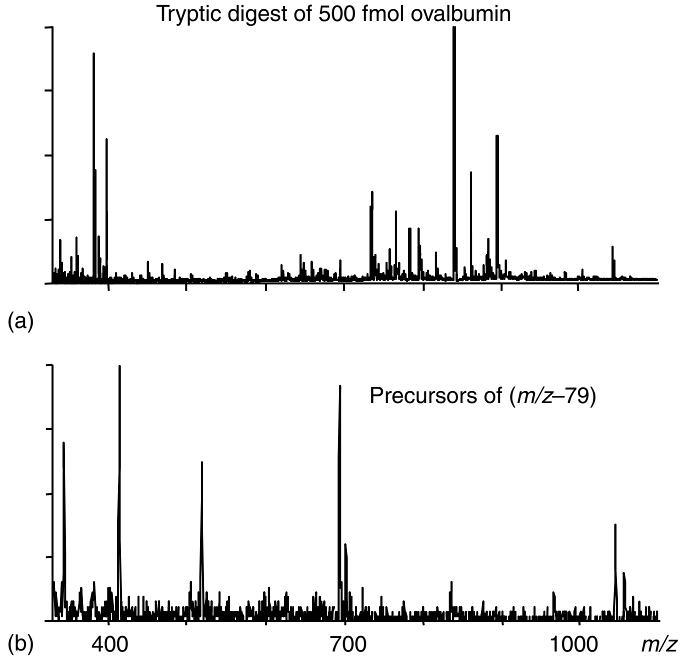

Figure 3 (a) Mass spectrum in negative ion mode of 500 fmol of a tryptic ovalbumin digest. Numerous peptide ion signals are apparent, however, it is not obvious which signals correspond to phosphorylated species. (b) Precursor ion experiment of ovalbumin that selectively detects the phosphorylated species giving rise to the characteristic PO_3^- fragment ion at *m/z* −79

Approaches to solve both of these limitations have recently been introduced:

1. Since deprotonated, anionic species can also be generated from strongly acidic solutions (e.g., LC effluents), if a negative potential is applied to the electrospray ionization (ESI) needle tip during a normal LC/MS experiment, a precursor ion scan in the negative ion mode can still be performed with an experimental strategy described as follows: a precursor of *m/z* −79 experiment in negative ion mode is performed on the deprotonated peptide ions eluting from the column. An ion signal in the precursor ion experiment triggers switching of the polarity of the instrument to the positive ion mode and a fragment ion spectrum of the protonated species, whose deprotonated complement gave rise to the signal in the negative ion mode precursor ion experiment, is acquired (Le Blanc *et al*., 2003). While performing this experiment, an *m/z* difference of 2 has to be considered to account for mass difference between the deprotonated and protonated species. Furthermore, one has to account for the fact that the observed degree of deprotonation does not necessarily reflect the degree of protonation, for example, a doubly deprotonated species does not necessarily give rise to a doubly protonated species such that attempts to fragment the phosphopeptides of interest can fail and/or additional scans have to be performed.
2. Niggeweg *et al*. recently introduced a way to circumvent the problem of precursor ion experiments on quadrupole TOF instruments. Fragment ion spectra

for each precursor mass were not acquired, instead the first quadrupole was operated in rf-only mode, that is, all precursors eluting off the column at any given time were fragmented simultaneously. The assignment of the precursor ion giving rise to the fragment ion species of interest at a given time is accomplished by correlating the LC elution profiles of the reporter ion(s) with the different peptide species eluting at that given moment. Possessing information about the exact elution time and exact precursor *m/z* value allows directed sequencing experiments to be performed in a consecutive LC/MS experiment of the same sample (Niggeweg *et al*., 2004).

3.4. Constant neutral loss scanning

The second fragmentation-specific detection method is the constant neutral loss scanning experiment that utilizes the characteristic neutral loss of phosphoric acid (H_3PO_4) from the phosphorylated species. This neutral loss reaction can be of significant abundance in triple quadrupole instruments or quadrupole TOF instruments, and is normally the predominant fragmentation in quadrupolar ion trap mass spectrometers. Although this loss occurs under acidic conditions in positive ion mode (i.e., it is easily compatible with LC/MS experiments), certain problems are caused by the fact that neutral losses are also charge-dependent, that is, a neutral loss of 98 Da translates into a *m/z* difference of 49 or 32.6 for doubly and triply charged species, respectively. Another problem with this method is a result of the low-resolution instruments (ion traps and triple quadrupole instruments) normally used for this type of experiment, where a loss of *m/z* 32 (methanesulfenic acid CH_3SOH) that occurs from a doubly charged peptide containing an oxidized methionine residue can be mistaken for a loss of a phosphoric acid moiety from a triply charged species. This is a particular problem when fast, low-resolution/low-accuracy scans are performed.

An interesting combination of the neutral loss and the brute force approach can be easily realized in quadrupole ion traps (*see* Article 9, **Quadrupole ion traps and a new era of evolution**, Volume 5) during a standard LC/MS run by triggering an MS^3 experiment when a peptide selected for fragmentation during a normal data-dependent acquisition displays a characteristic neutral loss of *m/z* 49 or 32.6 (see Figure 4). This MS^3 experiment of the "dephosphorylated" species (dephosphorylated in this context refers to the loss of H_3PO_4 and not HPO_3, as observed when proteins are treated with phosphatases) provides sequence information such that the position of the newly formed dehydroalanine and/or dehydroaminobutyric acid residues and hence the localization of the former site of phosphorylation can be determined. Although such an approach still requires that the species of interest is selected for fragmentation (many phosphorylated species are found in substoichiometric amounts making this an unlikely event), it allows one to selectively spend valuable measuring time on species of interest, thereby increasing the chances of an unambiguous localization of the phosphorylation sites (Beausoleil *et al*., 2004).

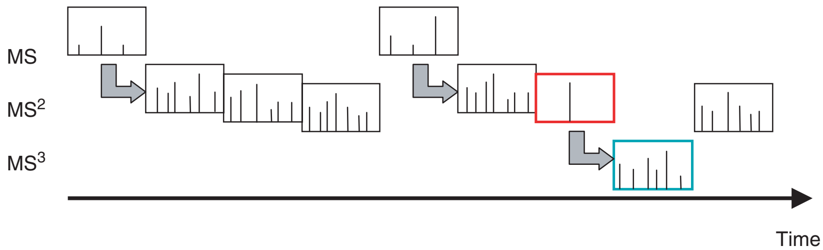

Figure 4 Schematic workflow of the data-dependent pseudoneutral loss/MS^3 experiments. The three most intense peptide ion signal are chosen for subsequent peptide sequencing by MS^2 after a survey MS. If one of the product-ion spectra shows a characteristic loss of phosphoric acid as major fragment ion (see red MS^2 spectrum), this particular fragment ion is further sequenced in an MS^3 experiment, often enabling the unambiguous localization of the phosphorylation site. Subsequently, the instrument returns to its normal data-dependent MS-MS^{2}cycle

3.5. Selective enrichment

Several different strategies for the selective enrichment of phosphopeptides and phosphoproteins have been devised. These are either based on antibodies or on affinity chromatographic methods utilizing the special physicochemical properties of phosphomonoesters, that is, phosphopeptides and phosphoproteins. It should be noted that the two approaches are somewhat complimentary because antibodies work much better for proteins, whereas affinity chromatographic approaches are more applicable to phosphopeptides.

3.6. Phosphospecific antibodies

Several commercial antibodies against generic motifs containing phosphoserine, phosphothreonine, and phosphotyrosine residues are available. The anti-phosphotyrosine-specific antibodies have been used in numerous studies for the selective enrichment of tyrosine-phosphorylated proteins, subsequent protein identification, and phosphorylation mapping, and hence have demonstrated their applicability (see Figure 5 and e.g., Godovac-Zimmermann *et al.*, 1999; Steen *et al.*, 2002).

Nevertheless, it should be noted that the different commercial monoclonal anti-phosphotyrosine antibodies such as 4G10 (Upstate) or RC20 (Transduction Laboratory) do show different specificities to an extent that a mixture of different anti-phosphotyrosine antibodies should be used in order to enrich for as many different tyrosine-phosphorylated species as possible. The performance of the commonly used anti-phosphotyrosine antibodies for enrichment/affinity purification is superior to the performance of the commercially available anti-phosphoserine and -threonine antibodies that do not show good specificity or yields of enrichment when used for immunoprecipitation (Gronborg *et al.*, 2002). However, Cell Signaling Technology has since shown that antibodies raised against peptide

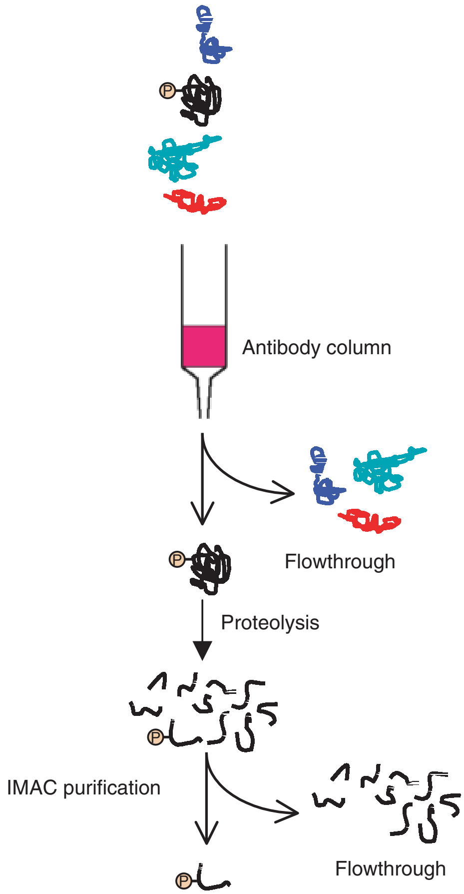

Figure 5 A general strategy using antibodies and immobilized metal affinity chromatography (IMAC) to enrich for phosphoproteins and subsequently for phosphopeptides

libraries composed of specific phosphorylated consensus motifs can be very useful for affinity purification of proteins containing the motif (Gronborg *et al*., 2002; Zhang *et al*., 2002a).

Antibodies are normally used for the enrichment of phosphorylated proteins although a recent study showed that antibodies can also be applied to phosphopeptides (Rush *et al*., 2005).

3.7. *Affinity chromatography*

It has been known for almost 20 years that phosphorylated species have a high affinity to Fe^{3+}-ions and that immobilizing this transition metal ion using different chelators provides a means to selectively enrich for phosphoproteins and phosphopeptides by Immobilized Metal Affinity Chromatography (IMAC; see Figure 6).

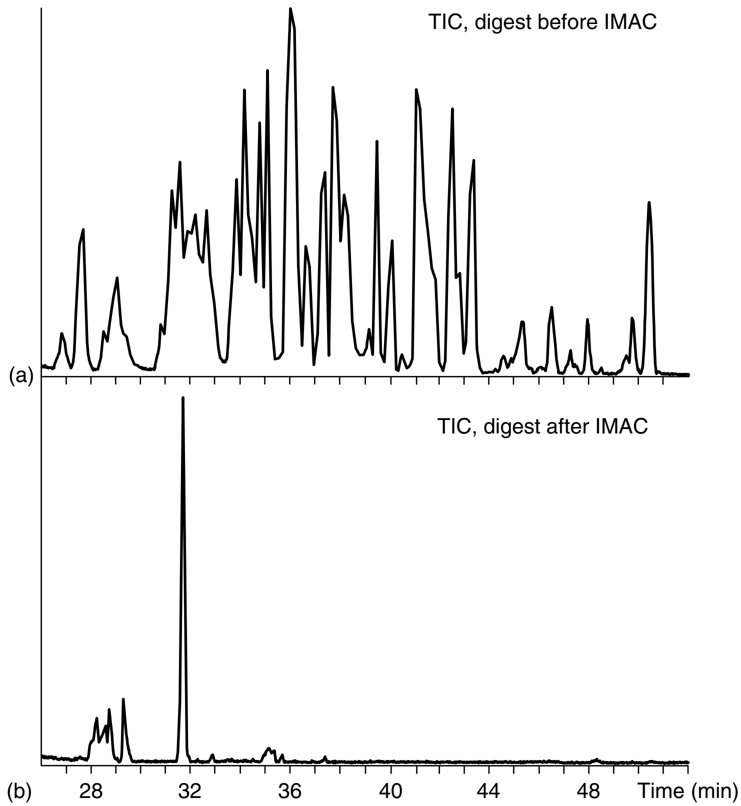

Figure 6 (a) The total ion chromatogram (TIC) of a tryptic digest of a phosphoprotein without immobilized metal affinity purification (IMAC). (b) The TIC of the same digest after IMAC enrichment of the phosphopeptides

Different metal cations and chelators have been tested and the most useful proven cations and chelators for proteomic purposes appear to be Fe^{3+}, Ga^{3+}, and ZrO^{2+}, and immobilized iminodiacetic acid (IDA) (e.g., POROS MC from Applied Biosystems) and nitrilotriacetic acid (NTA) (e.g., Silica-NTA from QIAGEN). These conclusions are based on studies testing the binding and the elution efficiencies of phosphorylated species. The question as to which combination is "the best" is debatable and is probably dependent on the particular sample and the operator's preference and experience (Nuhse *et al*., 2003; Posewitz and Tempst, 1999). Additional issues of concern with respect to IMAC for the enrichment of phosphopeptides are specificity (false-negatives) and selectivity (false-positives), that is, loss of some phosphorylated species and nonspecific binding of unphosphorylated peptides. The former issue is crucially dependent on the sample preparation and bed volume; that is, buffers with high salt concentrations or phosphate-based buffers severely affect the binding of phosphorylated species in general and underdimensioned bed volumes are biased toward multiply phosphorylated species (due to replacement-chromatography type processes). The selectivity of IMAC is complicated by amino acids within peptides with acidic

(Glu and Asp) and electron donor functionalities (e.g., His, Cys), which can show affinities to immobilized cations based on ionic and polar interactions. To increase the selectivity, Ficarro *et al*. devised a change in the established IMAC enrichment protocol for large-scale phosphoproteome studies by masking the acidic side chains of glutamic and aspartic acid residues by esterification (Ficarro *et al*., 2002). The use of this procedure is still debated (Brill *et al*., 2004), and there might be a sample-dependent trade-off between losses due to additional derivatization steps, increased complexity due to incomplete derivatization and side reactions, and lower selectivity.

Other strategies for the enrichment of subsets of phosphopeptides are based on the strong anionic character of the phosphomoiety at pH values > 2. The overall charge state of phosphorylated tryptic peptide is reduced to 1+ or less at a pH of 3 provided no additional basic residues besides the C-terminal lysine and arginine of tryptic peptides are present in the peptides. Thus, cation exchange beads can be used to enrich for phosphopeptides by collecting the flowthrough or the early/low salt fractions (Beausoleil *et al*., 2004). This is complemented by anion exchange strategies, by selecting salt concentrations at which predominantly phosphorylated species, especially multiply phosphorylated species, bind to anion exchange material and unphosphorylated peptides do not bind to the anion exchange material (Nuhse *et al*., 2003).

Although ion exchange strategies do not show both the specificity and selectivity of IMAC purification, they are still extremely useful for the enrichment of a subset of phosphopeptides and/or providing a method to reduce the complexity of the sample due to their robustness and superior capacity.

3.8. Derivatization of the phosphomoiety

The only enzymatic reaction on protein- or peptide-linked phosphomoieties that has been described (to our knowledge) is the complete removal of the phosphate group with phosphatases, which regenerates the original protein/peptide such that no information pertaining the site of phosphorylation is obtained. Thus, chemical means have to be exploited for the derivatization of the phosphomoiety leading to selective detection or enrichment of the original phosphopeptides. So far two different chemical strategies have been described:

1. Zhou *et al*. (2001) described a selective derivatization of the phosphomoiety utilizing 1-Ethyl-3-(3-dimethylaminopropyl)-carbodiimide (EDC) chemistry subsequent to a stepwise protection of the different functional groups within the peptides. This approach led to the formation of thiol-containing phosphoamidates, allowing the selective immobilization and purification of the phosphorylated species. Although conceptually interesting, this approach proved to be difficult because of the six different reaction steps and numerous reversed-phase purifications in between these reactions, compromising the throughput and sensitivity of this approach.
2. The other widely tried and tested chemical derivatization strategy applicable to serine and threonine phosphorylation, but not to tyrosine phosphorylation, is

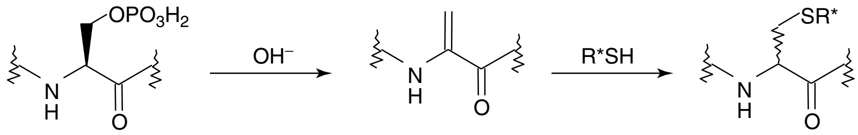

Figure 7 A reaction scheme showing the derivatization of phosphoserine residues using the β-elimination/Michael addition strategy. Please note that the former L-serine residue is racemized such that diastereomeric peptide species are often separated by LC

based on β-elimination of the phosphomoiety followed by a Michael addition of a strong nucleophile, such as a thiol to the in situ formed dehydroalanine and/or dehydro-2-aminobutyric acid (Meyer *et al*., 1986) (see Figure 7). Numerous thiols have been used for this derivatization strategy, enabling the specific detection of phosphopeptides based on identification of characteristic peak pairs (Molloy and Andrews, 2001); by precursor ion scanning in positive ion mode (Steen and Mann, 2002); using specific proteolytic cleavages (Knight *et al*., 2003; Rusnak *et al*., 2002); by allowing the selective immobilization utilizing solid-phase chemistry approaches (McLachlin and Chait, 2003; Qian *et al*., 2003); and using avidin-biotin interactions (Oda *et al*., 2001). An additional advantage of this β-elimination/Michael addition approach is that isotopically labeled compounds can be incorporated, which allow for the relative quantitation of protein phosphorylation (see below). However, this approach has limitations: (1) the reaction conditions leading to partial hydrolysis (Steen and Mann, 2002), (2) side reactions with unmodified serine and threonine residues (Li *et al*., 2003; McLachlin and Chait, 2003), (3) side reactions with other serine and threonine modifications such as O-glycosylation (Wells *et al*., 2002), or (4) side reactions with modified and incompletely reduced cysteine residues (Steen and Mann, 2002). This indicates that the application of this chemical derivatization strategy to phosphopeptide mapping of substoichiometric phosphopeptides ($<5\%$) may be problematic.

3.9. *Other strategies for the phosphorylation analysis*

One commonly used approach for the identification of phosphopeptides within mixtures utilizes alkaline phosphatase for the complete dephosphorylation of the sample. Acquiring spectra – usually MALDI-TOF mass spectra – before and after the phosphatase treatment allows the unambiguous identification of phosphopeptides based on the mass shift of 80 Da or multiples thereof (Larsen *et al*., 2001; Yip and Hutchens, 1992). However, since the enzymatic dephosphorylation regenerates the original unmodified peptide structure, it is not possible to determine the site of original phosphorylation using the phosphatase-treated sample. For the detailed phosphorylation site determination, another fraction of the sample has to be reanalyzed, but since the masses of the phosphopeptides are known sensitive and time efficient, directed experiments can be performed.

Another alternative for qualitative and quantitative (see below) analysis of protein phosphorylation was introduced by Lehmann and coworkers (Wind *et al*.,

2001). They coupled liquid chromatography to inductively coupled plasma (ICP) mass spectrometry. In ICPMS, the sample is atomized/ionized at 8000 K using an inductively coupled plasma, which allows for the selective detection of phosphorylated species eluting from the reversed-phase column based on the presence of a signal for $^{31}P^{+}$, an element that is not present in unmodified proteins/peptides. Such an experimental setup enables the identification of a peptide as being phosphorylated species, and accurate quantitation of the phosphorylated species can be made. However, as the peptides are completely atomized, it is not possible to identify the phosphopeptide and/or to determine the site of phosphorylation, that is, further "traditional" LC/MS experiments have to be performed. This can be done in a more directed way, since the retention times of the phosphorylated species are known.

3.9.1. Quantitation of protein phosphorylation

Since protein phosphorylation is highly dynamic, it becomes increasingly apparent that it is no longer sufficient to merely identify the site of phosphorylation. Information pertaining to the extent of phosphorylation, and/or the comparison between the phosphorylation states of different samples must also be acquired. Although quantitative proteomics is in its infancy, several approaches, mainly based on stable isotope labeling, have been introduced (reviewed in Lill, 2003; Steen and Pandey, 2002), and it is obvious that the quantitation of protein phosphorylation combines the difficulties of quantitative proteomics with the problems encountered in modification-specific proteomics. In addition, quantitation of phosphorylation has two aspects: (1) the relative quantitation to determine the increase or decrease of phosphorylation in different samples and (2) absolute quantitation to determine the degree of phosphorylation.

Apart from the methods that aim to reduce complexity of the samples by labeling particular amino acid residues, for example, ICAT (Gygi *et al*., 1999; *see also* Article 23, **ICAT and other labeling strategies for semiquantitative LC-based expression profiling**, Volume 5), all other described methods are, in principle, applicable to the relative quantitation of phosphorylation (or modifications in general), especially if combined with the different specific enrichment or detection strategies described above. Examples for application of metabolic isotopic labeling strategies or peptide derivatization approaches subsequent to proteolysis of samples for the quantitation of protein phosphorylation can be found in Ibarrola *et al*. (2003) and Bonenfant *et al*. (2003).

In addition, several phosphospecific mass spectrometry–based relative quantitation methods have been introduced. One of them is based on β-elimination/Michael addition utilizing pairs of isotopologues for the labeling of the different samples. Proofs of concept have been provided by Weckwerth *et al*. (2000) who used normal or deuterium-labeled ethanthiol or by Goshe *et al*. (2001) who combined β-elimination/Michael addition with the ICAT strategy by using isotopologues of thiol-terminated biotin derivatives – a strategy coined PhIAT for Phosphoprotein Isotope-Coded Affinity Tag. Both of these approaches suffer from the same limitations of β-elimination/Michael addition as described above and thus should be applied and the results interpreted with caution.

Another very sensitive and precise approach that can be used for the quantitation of proteins and other general modifications makes use of synthetic, isotopically labeled peptides as internal standards, which can be spiked into the samples in defined quantities (Ayad *et al*., 2003; Gerber *et al*., 2003). Using this method, it is sufficient to ensure that equal amounts of the synthetic phosphopeptide are added to the different samples for relative quantitation, whereas for absolute quantitation the synthetic peptide must be quantitated by, for example, amino acid analysis such that defined amounts of the internal standard are added to the sample(s). This method shows very good accuracies and detection limits. If a particular phosphorylation site is being monitored in a large number of samples, the method is very cheap; however, as the method entails peptide synthesis, purification, and quantitation, it is expensive for single-use experiments.

Other methods for the absolute quantitation of the degree of phosphorylation entail splitting the sample and labeling the two fractions with different isotopologues prior to dephosphorylation of one of the fractions. Subsequently, the two fractions are combined and analyzed by mass spectrometry; the ratio of the two dephosphorylated isotopologues species enable the calculation of the degree of phosphorylation (Hegeman *et al*., 2004; Zhang *et al*., 2002b).

In addition to the different quantitation approaches that are based on the comparison of the signal intensities of isotopologues, there is an increasing notion that the current LC/MS setup with autosampler is sufficiently quantitative and reproducible such that semi quantitative information with respect to the degree of phosphorylation can be derived simply by monitoring the peak intensity during an LC/MS experiment. Using this setup provides a general, cheap, and fast way to quantitate protein phosphorylation. In order to normalize for run-to-run variations and for different amounts of starting material in the different samples (a point that is often ignored in many methods and studies), the signal intensity of one or more "robust" peptides from the numerous unmodified peptides identified from the phosphorylated protein of interest can be used as an internal standard (Ruse *et al*., 2002; Steen *et al*., 2005). This allows for the relative quantitation of protein phosphorylation.

Assuming that the decrease (increase) of the ion signal intensity of the phosphorylated species is reflected by the increase (decrease) of the ion signal intensity of the unphosphorylated complement, it is possible to calculate the ratio of the ionization/detection responses of both peptide species. This in turn allows for the calculation of the degree of phosphorylation by simply comparing the signal intensities of the phosphorylated and the unphosphorylated peptide without assuming equal ionization/detection responses of the two species. At least two different measurements are necessary for a singly phosphorylated species, whereas three different states are necessary to calculate the relative ionization/detection responses for doubly phosphorylated peptides and their singly phosphorylated and unphosphorylated complements, and so on. Once the relative ionization/detection responses have been determined, they can be used for the particular peptide signals in following experiments – presuming the experimental and instrumental parameters did not change – such that the extent of phosphorylation can easily be calculated even in a single sample. If only one sample is available, phosphatase treatment for complete or partial dephosphorylation can be used to generate samples

representing different degrees of phosphorylation, which can then be used to calculate the extent of phosphorylation (Steen *et al*., 2005).

4. Conclusion and outlook

The large number of different mass spectrometric methods available for the analysis of protein phosphorylation underscores the notion that no single method provides a comprehensive phosphorylation map of a protein. As such, numerous methods have to be applied and correspondingly larger amounts of protein are necessary for phosphorylation mapping in comparison to simple protein-identification studies (Chen *et al*., 2002; Vihinen and Saarinen, 2000). Global phosphoproteomic experiments pose different problems to single protein phosphorylation mapping; in such cases, the goal is to identify as many phosphorylation sites as possible. This generates a huge amount of valuable information such that missing some phosphorylation sites is irrelevant. Impressive progress has been made in this field starting with the yeast phosphoproteome study by Ficarro *et al*. (2002) who identified several hundreds of phosphorylation sites. Since this study, several other studies have been published, which clearly show that large phosphoproteomics experiments can be performed (Beausoleil *et al*., 2004; Nuhse *et al*., 2003). However, to avoid terming these large-scale phosphoproteomic studies as "interesting stamp collections", large-scale quantitative phosphorylation studies should be carried out as well. These types of experiments would allow the comparison of phosphorylation states between, for example, different cell states, thus providing a more biological insight into signaling processes. Unfortunately, most of the quantitative approaches only allow for the comparison of two states/samples. However, these types of studies will become a reality with the novel labeling reagent such as the iTRAQ from Applied Biosystems that facilitates the comparison of up to four cell states/samples and with the implementation of software that allows the robust quantitation of particular peptide ion signals without any labeling. This limitation should be solved and more quantitative phosphoproteomic studies can be expected in the near future.

Acknowledgments

The authors would like to thank their former and present colleagues at University of Southern Denmark, Harvard Medical School and MDS-SCIEX. In addition, we would like to apologize to all those authors whose work in the field of mass spectrometric analysis of protein phosphorylation could not be cited due to space constraints.

Specialist Review

Structure/function of *N*-glycans

Miriam V. Dwek
University of Westminster, London, UK

Susan Brooks
Oxford Brookes University, Oxford, UK

1. Background – the importance and function of N-linked glycosylation

There is an increasing interest in the posttranslational modification of proteins, and among these modifications, glycosylation appears to be one of the commonest and most functionally significant. Glycosylation is an extremely common event and analysis of gene sequences reveals that more than 50% of all proteins have one or more glycosylation site (Apweiler *et al*., 1999; *see also* Article 65, **Structure/function of *O*-glycans**, Volume 6, Article 66, **GPI anchors**, Volume 6, and Article 72, **O-linked *N*-acetylglucosamine (*O*-GlcNAc)**, Volume 6). Despite this, only a very small proportion of glycosylated proteins have been fully characterized as the analysis of glycans remains a technically challenging and specialist field.

2. Glycosylation of proteins – a brief overview

The oligosaccharides or glycans synthesized by human cells are composed of seven monosaccharide units: glucose (Glc), galactose (Gal), mannose (Man), fucose (Fuc), *N*-acetylglucosamine (GlcNAc), *N*-acetylgalactosamine (GalNAc), and sialic or neuraminic acids (SA). SA is a negatively charged molecule and its presence often alters the chemical properties of the glycan substantially. The individual monosaccharides link together in α- or β-linkages between different carbon atoms of their ring structures (e.g., $\alpha 1 \rightarrow 3$, $\beta 1 \rightarrow 4$, $\alpha 2 \rightarrow 3$ etc.), giving rise to a bewildering heterogeneity of potential glycan structures. Although all the theoretical permutations do not exist in vivo, glycans still remain an extraordinarily structurally diverse group of compounds and their biochemical analysis is technically challenging.

3. What are N-linked glycoproteins?

Glycoproteins are proteins containing one or more covalently linked carbohydrate group(*see* Article 62, **Glycosylation**, Volume 6). In N-linked glycoproteins, the

oligosaccharide chain is attached by its first monosaccharide residue, GlcNAc, in a β-N-glycosidic bond to the nitrogen of the amino group of asparagine (Asn) on the polypeptide chain.

4. The enzymes of glycosylation – glycosidases and glycosyltransferases

Unlike proteins and nucleic acids, oligosaccharides are not directly the products of genes; rather, they are built by the coordinated activity of glycosidases (enzymes that cleave glycans) and glycosyltransferases (enzymes responsible for the attachment of monosaccharide units). Over 250 different enzymes are known to be involved in mammalian glycan synthesis, and the activity of 30 or more enzymes can be involved in synthesis of a single N-linked oligosaccharide chain.

Several enzymes are critical in the early stages of N-linked glycan synthesis. The first important enzyme is the oligosaccharyltransferase (OST), a multimeric enzyme complex, which is responsible for attaching a preformed oligosaccharide precursor from a dolichol lipid intermediate to the amide nitrogen of the Asn residue of the nascent polypeptide. Mannosidases and glucosidases then trim the large oligosaccharide precursor. Once the N-linked oligosaccharide has been attached to the protein and trimmed, it is extended by the sequential addition of monosaccharides. These monosaccharides are added via a transglycosylation reaction, catalyzed by a specific glycosyltransferase: here, a monosaccharide is transferred from a high-energy nucleotide donor, commonly uridine 5′-diphosphatase (UDP), guanosine 5′-diphosphatase, (GDP) or cytidine 5′-diphosphatase (CDP), onto the oligosaccharide acceptor. The high-energy nucleotide donors are synthesized in the cytosol and transported across the membrane of the endomembrane system by antiporters that ensure the reciprocal return of spent nucleotides to the cytosol. This step is essential for successful glycosylation as the presence of spent nucleotides is potently inhibitory to transglycosylation reactions.

Until recently, it was believed that a single glycosyltransferase was responsible for catalyzing the transglycosylation reaction between a given donor and acceptor to yield a single, specific linkage – often referred to as the “one enzyme – one linkage rule”. It is now known that although usual, this is not universally the case. Sometimes, more than one enzyme, usually belonging to the same enzyme family, can catalyze identical linkages, and also, sometimes, a single enzyme may be capable of catalyzing more than one reaction.

5. Location and retention of the enzymes of glycosylation in the secretory pathway

As the enzymes of glycosylation act sequentially in trimming and building oligosaccharides, so, generally, they are located along the secretory pathway in the same sequence in which they act to modify oligosaccharides. For example, the α-mannosidase I involved in early trimming of N-linked glycans is located in the *cis*-Golgi; the *N*-acetylglucosaminyltransferase I involved in early elongation is located

in *medial*-Golgi and β1,4 galactosyltransferase and α2,6 sialyltransferase involved in terminal glycosylation are located in the *trans*-Golgi network. The situation is, however, slightly more complex than this, with some glycosyltransferases found throughout the Golgi stacks, and others being located in different parts of the secretory pathway in different cell types, or in the same cell types under different physiological conditions, at different stages in development or in disease. Such enzyme subcompartmentalization may control the types and range of oligosaccharides synthesized by a cell. The regulation of glycan synthesis, which is not well understood, is the subject of much conjecture. Several theories have been put forward to explain the positioning of enzymes of glycosylation within the secretory pathway and their retention there, as opposed to their being delivered to the plasma membrane and/or other parts of the cell along with other proteins passing through the secretory pathway (Colley, 1997). As there is little sequence homology between glycosidases and glycosyltransferases from different families, a common Golgi retention signal, analogous to KDEL/HDEL endoplasmic reticulum localization sequence or akin to the mannose-6-phosphate system responsible for lysosome targeting, is unlikely. However, they do share a common domain structure. They are all type II transmembrane proteins consisting of a cytoplasmic tail, a signal anchor transmembrane domain, a stem region, and a large luminal catalytic domain. Their positioning and retention in the Golgi apparatus may be related to the conformation of their shared domain structure.

Two major theories are currently proposed to explain Golgi retention and positioning. The first suggests that differing concentrations of cholesterol in the lipid bilayer in different parts of the endomembrane system result in membranes with different characteristics of thickness and stiffness. It has been proposed that glycosyltransferases locate to different microdomains that have characteristics appropriate to their particular transmembrane segment and that their short transmembrane region allows retention within the Golgi apparatus because they are not physically able to incorporate into cholesterol-rich transport vesicles destined for the plasma membrane. An alternative "kin recognition" model proposes that glycosyltransferases that are involved in specific parts of the glycobiosynthetic pathway aggregate together through interactions between their stem regions into insoluble homo- or hetero-oligomers too large to enter transport vesicles. Further interaction between cytosolic components and the enzyme complex with Golgi apparatus membrane proteins may additionally anchor these complexes in place (Nilsson *et al*., 1993). There have also been suggestions that the pH gradient from the ER (endoplasmic reticulum) through the Golgi apparatus may play a role in correct localization of the glycosyltransferase enzymes.

6. Regulation of glycosyltransferase expression and activity – what glycans are synthesized?

The factors that determine the glycosylation repertoire of a cell are multiple, tissue specific, and highly regulated during differentiation and sometimes cellular proliferation, and are not well understood. Many glycosidases and glycosyltransferases

are constitutively expressed at low levels in all mammalian somatic cells, presumably to provide the everyday machinery of glycosylation for the biosynthesis of cellular glycoconjugates. Cells may also upregulate the expression of specific glycosyltransferases in response to changes in conditions, to supply a need for higher levels of expression of glycosylated molecules.

Glycosyltransferase and glycosidase expression appears to be regulated predominantly at the level of transcription but differential processing of mRNA, alterations in mRNA stability and differences in efficiency of translation may also influence final enzyme activity. The expression of closely related isoenzymes with different levels of activity or substrate preference appears to be one mechanism by which differential glycosylation is achieved.

Other factors that influence the glycosylation profile of the cell are the availability of sugar donors, competition for glycoprotein or sugar donor between different competing glycosyltransferase enzymes, competition for glycosyltransferase enzymes between different potential glycoproteins, the conformational structure of the protein, and the rate at which the glycoprotein passes through the secretory pathway – which influences contact time of transferase with substrate. Enzymes that have different pH requirements may also function optimally in different parts of the secretory pathway as the internal pH decreases from ER to *trans*-Golgi network.

7. N-linked protein glycosylation

N-linked protein glycosylation is much better understood than O-linked glycosylation because of the range of chemical inhibitors of various parts of the N-linked biosynthetic pathway which have facilitated its careful study (Elbein, 1987). N-linked glycosylation begins with the synthesis in the cytoplasm of a branched oligosaccharide ($Man_5GlcNAc_2$) linked to a dolichol molecule embedded in the membrane of the ER. The $Man_5GlcNAc_2$ structure is synthesized by the action of, sequentially, first, an *N*-acetylglucosaminylphosphotransferase enzyme, which catalyzes the reaction Dol-P + UDP-GlcNAc → GlcNAc-P-Dol + UMP; then, an *N*-acetylglucosaminyltransferase catalyzes the addition of a GlcNAc (from the donor UDP-GlcNAc) to form GlcNAc(β1 → 4)GlcNAc-P-Dol; this is called the *chitobiose core*. The chitobiose core is then acted upon by mannosyltransferase I and a mannose residue (from the donor GDP-Man) is added to yield Man(β1 → 4)GlcNAc(β1 → 4)GlcNAc-P-Dol. Then, mannosyltransferases II to IV come into play, adding, sequentially, three mannose residues to give the branched dolichol-linked oligosaccharide precursor $Man_5GlcNAc_2$ structure, illustrated in Figure 1(a).

This cumbersome hydrophillic structure, is flipped across the hydrophobic lipid bilayer of the plasma membrane of the ER, from the cytoplasmic face of the membrane and onto the lumenal face, in a process that remains incompletely understood (Helenius *et al*., 2002) but includes the Rft1 flippase protein (Helenius *et al*., 2002). The $Man_5GlcNAc_2$ structure is then extended by the addition of four mannose and three glucose units to form an oligosaccharide intermediate $Glc_3Man_9GlcNAc_2$ (Figure 1b). This oligosaccharide intermediate is then attached to an Asn residue (within a consensus sequence Asn-Xaa-Ser/Thr, where Xaa is any amino acid except proline) of the nascent polypeptide chain. Attachment

of the oligosaccharide intermediate to the Asn is catalyzed by the enzyme oligosaccharyltransferase (OST). N-linked glycosylation is thus a cotranslational event – it commences during the synthesis of the polypeptide.

The oligosaccharide intermediate is then sequentially trimmed by the action of first α-glucosidase I, which cleaves the terminal Glc residue, then α-glucosidase II, which cleaves the remaining two terminal Glc residues, then α-mannosidase, which removes a terminal Man residue. This yields the structure $Man_8GlcNAc_2$, illustrated in Figure 1(c). This trimming is important for a number of reasons. First, α-glucosidase I acts while the oligosaccharide intermediate is still attached to the OST and is necessary for its release. Secondly, trimming of the Glc residues is an important control mechanism in protein folding (Parodi, 2000). Folding glycoproteins are recognized by two ER resident lectins, membrane-bound calnexin, and

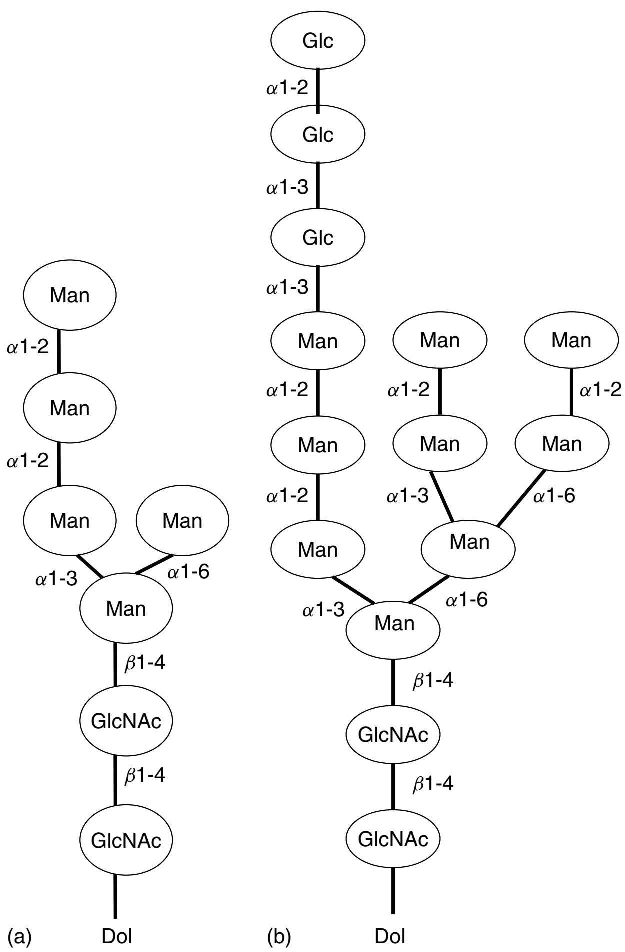

Figure 1 (a) Man5GlcNAc2 oligosaccharide precursor. (b) Glc3Man9GlcNAc2 oligosaccharyl intermediate. (c) $Man_8GlcNAc_2$. (d) $Man_5GlcNAc_2$. (e) A high mannose–type N-linked glycan. (f) A complex-type N-linked glycan

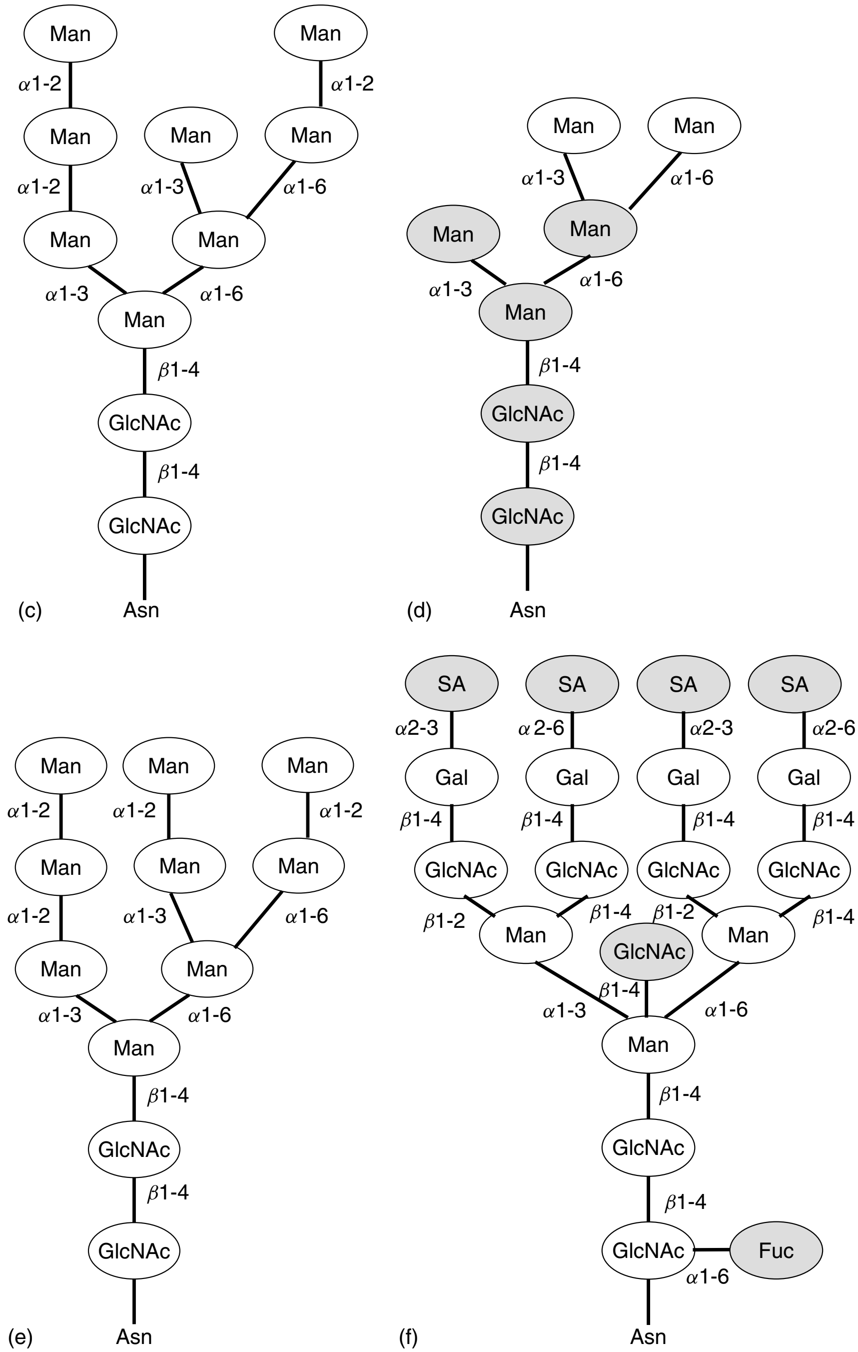

Figure 1 (*continued*)

its soluble homolog calreticulin. These lectins recognize the $\alpha 1 \rightarrow 3$ linked Glc of the partially trimmed $Glc_1Man_9GlcNAc_2$ intermediate, which is created from $Glc_3Man_9GlcNAc_2$ by the action of glucosidases I and II. Once they have bound the lectins, disulfide bonds are formed between cysteine residues on the polypeptide chain of the glycoprotein. If the protein is now correctly folded, the further action of glucosidase II results in the removal of the final $1 \rightarrow 3$ linked Glc yielding $Man_9GlcNAc_2$ and the calnexin and calreticulin are released from the glycoprotein. This signals the exit of the correctly folded protein from the ER and its transport to the Golgi apparatus. If, however, it is not properly folded, the physical features of the misfolded protein, for example, the presence of hydrophobic patches, trigger the action of UDP:Glc: glycoprotein glucosyltransferase (GT), which reglucosylates the oligosaccharide intermediate. The glycoprotein is then once again recognized by the lectins and returns through the cycle of reglucosylation and folding until correct folding is achieved. GT thus acts as a sensor of glycoprotein misconformation. Proteins that are terminally misfolded are eventually transported from the ER into proteosomes in the cytosol and degraded.

Another important signaling oligosaccharide is that which targets glycoproteins to the lysosome for degradation. This structure is mannose-6-phosphate and it is synthesized by the modification of the $Man_8GlcNAc_2$ intermediate structure by the addition of phosphorylated GlcNAc (catalyzed by the action of GlcNAc-1-phosphotransferase) to the subterminal Man; the GlcNAc is then cleaved, leaving mannose-6-phosphate. This structure is recognized by a mannose-6-phosphate receptor on the lysosome.

If the protein is successfully folded, it is transported to the Golgi apparatus and glycosylation continues. Further Man residues are removed to yield a $Man_5GlcNAc_2$ structure, illustrated in Figure 1(d), which may then either be trimmed further and extended by the addition of other monosaccharides or extended without further trimming. A heterogeneous range of branching N-linked glycans are thus possible; in general, the function of this microheterogeneity in glycan structure is poorly understood.

Nevertheless, all N-linked glycans share a common trimannosyl core, shaded in Figure 1(d), and are classified as (1) high mannose, (2) complex, or (3) hybrid type. High mannose type have between five and nine Man units attached to the trimannosyl core, illustrated in Figure 1(e); complex type have no further Man units attached to the trimannosyl core, but have branches containing chains of the disaccharide GlcNAc($\beta 1 \rightarrow 4$)Gal (termed polylactosamine chains). An example is given in Figure 1(f). Hybrid type, as the name suggests, contain a mixture of structural features of both high mannose and complex types. The hybrid and complex type N-linked glycans are significant because their synthesis appears to be a late evolutionary event that is associated with animals possessing a blood circulatory system. This is of relevance to the biotechnology industry as it is the cells of simpler organisms, such as bacteria, yeasts, plants, and insects that are commonly used for the production of recombinant proteins. The N-linked glycans that these cells synthesize differ significantly from those of human cells, and, if they are destined for human use, may result in them having unpredictable biological activities, serum half-life or immunogenicity.

The antennae of N-linked glycans may also be further elaborated by diverse glycan structures. A bisecting GlcNAc can be attached to the trimannosyl core and fucose residues can be attached to various antennae structures. Antennae are often terminated by $\alpha 2 \rightarrow 3$ or $\alpha 2 \rightarrow 6$ linked charged sialic acid residues. These features are illustrated, shaded, in the complex-type N-glycan in Figure 1(f).

8. N-linked glycosylation – functional aspects

Our understanding of the function of N-linked glycans on proteins has been helped considerably by the availability of inhibitors that serve to prevent the normal biosynthesis of N-linked structures. Defining the function of N-linked glycans on proteins has often been difficult because of technical aspects related to their evaluation and this topic is considered in more detail later. Glycosylation influences numerous aspects of protein biochemistry; for example, correct protein folding, susceptibility to proteases, serum half-life and functional activity. Many of these characteristics are of particular significance with regard to recombinant proteins destined for potential human therapeutic use, and therefore a better understanding of glycosylation and its control is of great relevance to the burgeoning biotechnology industry (Brooks, 2004). The glycosylation of proteins is pivotal to many processes involving cell–cell interactions, for example, fertilization, embryogenesis and development, immune defense, inflammation, and in disease processes, including cancer metastasis (Dennis *et al*., 1999; Orntoft and Vestergaard 1999) and glycosylation is of relevance in diverse aspects of biology and medicine. Our understanding of the function of N-linked glycans on proteins has been greatly assisted by the availability of specific inhibitors that prevent the normal biosynthesis of N-linked structures; another crucial technology has been site-directed mutagenesis to evaluate the effect of preventing glycan occupancy at particular N-linked glycosylation sites. Using these, and other technical approaches, it has been possible to elucidate the function of N-linked glycosylation. Many examples exist in which N-linked glycosylation is known to play a crucial role in protein function and some examples of these are given below.

8.1. Protein structure

The importance of N-linked glycans in ensuring correct protein folding was mentioned briefly earlier. This aspect of N-linked glycosylation has received much attention and the crucial role of N-linked glycans in ensuring the correct physiological structure of proteins has been shown in a number of different biological systems. In the case of the immunoglobulin G (IgG), for example, the constant domains in the hinge region of IgG contain N-linked glycans and the $\alpha 1 \rightarrow 3$ branch of the trimannosyl core on one N-linked glycan interacts with the trimannosyl core on the other glycan. This interaction changes the conformation of the N-linked glycan structures to allow interaction with the binding pocket on the constant domain surface of the IgG. This is thought to be an important structural feature of N-linked glycans on IgG in later enabling monocyte binding.

8.2. Protein clearance

One of the best-described functions for N-linked glycosylation of proteins is in modulating the clearance of serum proteins from the circulation. The role of N-linked glycans in process was first discovered in the 1960s when the copper-transporting protein ceruloplasmin was found to have a much reduced serum half-life concurrent with an absence of sialic acid residues on its N-linked glycans. Since then, it has become recognized that a carbohydrate-binding protein (lectin) in the liver, the hepatic asialoglycoprotein receptor recognizes asialo- (sialic acid free) serum proteins. When asialylated proteins bind to the receptor, they are removed from the circulatory system and degraded in the lysosomes. This important receptor is responsible for the clearance of, amongst other proteins, erythropoietin, whose serum half-life is dramatically reduced when non-sialylated N-linked glycans are attached (Ashwell and Harford, 1982). Importantly, other lectin-receptors have been reported that bind to the monosaccharides found in N-linked glycans and further functions relating to the role of N-linked glycosylation in protein clearance are likely to be described.

8.3. Enzyme function

There are numerous accounts showing a role for N-linked glycans in enzyme function; these include altering the kinetics of enzyme-substrate interactions, maintaining appropriate tertiary structure of the enzyme, or alternatively, the glycans may be important for other aspects of enzyme function such as the binding of divalent cations. In the case of tissue plasminogen activator (tPA), a serine protease that converts plasminogen to plasmin and induces fibrinolysis, the N-linked glycans appear to have a multitude of important functions. For example, glycan occupation at Asn 184 has been shown to allow the formation of a double-chain form of tPA, which results in an increase in the size of the lysine binding site in fibrin thereby reducing fibrinolysis; additionally, glycosylation has been shown to modulate the kinetics of enzyme–substrate interaction of both tPA and its substrate plasminogen (which is itself variably glycosylated).

8.4. Hormone function

There is now considerable evidence, mostly from studies of the pituitary hormones that show N-linked glycans are important molecules in signaling events. The N-linked glycans attached to lutenizing hormone (LH), thyroid-stimulating hormone (TSH) and chorionic gonadotrophin (CG) has been shown to have a variety of functions. The first is to ensure the correct folding of the two (α and β) subunits on LH, FSH (follicle stimulating hormone), and CG, each of which contains one or two occupied N-linked glycosylation sites. The N-linked glycans, of LH rather than containing terminal Gal capped with SA contain terminal GalNAc variably capped with sulfate groups. The presence of the terminal GalNAc with/without sulfate is important for serum clearance of the hormones by the Kupffer cells of the liver and

acts as an important feedback signal to ensure that more LH is produced by the pituitary gland and subsequent induction of ovulation via the LH/CG receptor in the ovary. Notably, the enzymes involved in the attachment of GalNAc and sulfate to the LH fluctuate according to the levels of estrogen in the circulation (Bielinska and Boime, 1995).

In conclusion, the diversity of N-linked glycans and their role in a wide range of protein functions means that there is considerable interest in their structural analysis. The well-defined biosynthetic pathway for N-linked glycans has aided our study of this type of glycosylation. It is now widely accepted that N-linked glycosylation is often important for a range of physiological functions including to ensure correct protein folding, clearance of proteins from the circulation, and as signaling molecules.

Specialist Review

Structure/function of *O*-glycans

Anthony P. Corfield

University of Bristol, Bristol, UK

1. Introduction

Glycosylation is a major posttranslational modification affecting well over 50% of all proteins (Van den Steen *et al*., 1998; Varki *et al*., 1999). Recent developments in glycobiology have seen significant improvements in oligosaccharide sequencing, the establishment of databases of oligosaccharide structures, and clear demonstration of a range of biological functions associated with glycans. The *O*-glycans represent one of the three main groups of glycosylation modifications, the others being *N*-glycans and glycosylphosphatidyl inositol anchors (*see* Article 64, **Structure/function of *N*-glycans**, Volume 6 and Article 66, **GPI anchors**, Volume 6) (Varki *et al*., 1999; Brockhausen *et al*., 2001). *O*-glycans fall into several groups: (1) the oligosaccharides having GalNAc linked to serine or threonine, often termed *mucin type glycosylation*, which is the focus of this article; (2) *N*-acetylglucosamine linked to serine or threonine (*O*-GlcNAc) on cytosolic and nuclear proteins (*see* Article 72, **O-linked *N*-acetylglucosamine (*O*-GlcNAc)**, Volume 6), (3) Fucose and Glucose O-linked to serine or threonine in the epidermal growth factor domains in a variety of proteins; (4) O-mannosylation detected in mammalian systems and identified in dystroglycan and brain proteoglycans, together with the oligomannosyl glycans found in yeasts (*see* Article 71, ***O*-Mannosylation**, Volume 6) and finally, (5) proteoglycans, a large family of molecules with distinct structural and functional differences to the other groups listed here. This short review outlines the structural characteristics of the large number of oligosaccharides linked to serine and threonine through GalNAc, and groups the molecular and biological functions associated with the presence of these *O*-glycans. More detailed consideration of the processing of the *O*-glycan chains and their role in protein processing is covered elsewhere in this volume (*see* Article 70, ***O*-glycan processing**, Volume 6).

2. The structure of O-linked glycans

2.1. O-GalNAc oligosaccharide structure

Oligosaccharides in the Ser(Thr)-GalNAc class vary in size from a single GalNAc through disaccharides to chains with up to 18 or more sugar residues. The

larger oligosaccharides comprise three distinct regions: (1) a core unit linking the oligosaccharide chain to serine and threonine residues in the protein; (2) a backbone, found in extended glycans, but not always present; and (3) a peripheral nonreducing terminus, which is largely responsible for the considerable diversity found in the *O*-glycans (Schachter and Brockhausen, 1992).

Addition of a single GalNAc residue occurs in a small number of proteins under normal conditions. This has been termed *the Tn antigen* and has been used as a cancer marker as it is also expressed in many tumors.

Eight core classes have been identified and are shown in Table 1. Core 1 and Core 2 are the most common structures found, with lower occurrence of Core 3 and 4, while the remaining structures are relatively rare. The type of core has a direct influence on the final structure of the extended oligosaccharides and is also determined by the biosynthetic pathways outlined briefly below (see Figure 1 for an example of biosynthetic pathways for Core 1–4 structures (Brockhausen *et al*., 2001)). This has implications for disease-related changes where the core class is modified resulting in abnormal, cancer-related glycosylation. Branched chains are generated from Core 2 and Core 4, and these are also subject to predictable extension through the biosynthetic pathways. In larger extended oligosaccharide chains, a backbone made up of Galβ1-3/4GlcNAc repeat units may be found, and these include the i/I antigens that may remain as nonreducing terminal structures (Table 1 (Schachter and Brockhausen, 1992; Brockhausen *et al*., 2001)). The huge variation of *O*-glycan oligosaccharide structures arises from the decoration of the core, and backbone units by a variety of peripheral units. These modifications include fucosylation, sialylation, sulfation, acetylation, and methylation. Many of these peripheral units are structures with biological function such as the blood group and sialylated/fucosylated/sulfated antigens. Some examples from the large databases of *O*-glycan structures are given in Table 1.

2.2. *Identification of O-glycan sites*

The identification of those serine and threonine residues in peptide sequences that are selected for O-glycosylation does not follow the simple tripeptide sequon model for N-linked oligosaccharides. Potentially any serine or threonine may be a site, and in contrast to *N*-glycan sites, often appear as clusters. Peptide domains with high serine, threonine proline content have been identified in many proteins but no general consensus sequence has been identified. However, a series of general rules have been identified and an algorithm has been developed to predict O-glycosylation sites (Gupta *et al*., 1999; Thanka Christlet and Veluraja, 2001). The identification and characterization of the transferases that add the first GalNAc residues to the peptide (ppGaNTases) has shown that the selection of O-glycosylation sites is regulated at the enzyme level ((Ten Hagen *et al*., 2003) and see below) and explains, in part, the difficulty in predicting sites from primary sequence alone. A number of features can be identified that appear to govern the siting of *O*-glycans. First, a primary sequence preference can be identified, which varies for serine and threonine, reflecting the greater level of threonine substitution. Positioning of proline in the peptide adjacent to O-glycosylation sites has been

Table 1 Features of *O*-glycan structure. Structures are color-coded to show core (black), backbone, and peripheral regions

Nomenclature	Structure	Common name
Initial glycosylation with GalNAc		
GalNAc protein	GalNAcα-*O*-Ser/Thr	Tn antigen
Core classes		
Core 1	GalNAcα-*O*-Ser/Thr Galβ1-3	Thomsen Friedenreich (TF or T) antigen
Core 2	GlcNAcβ1-6 GalNAcα-*O*-Ser/Thr Galβ1-3	
Core 3	GalNAcα-*O*-Ser/Thr GlcNAcβ1-3	
Core 4	GlcNAcβ1-6 GalNAcα-*O*-Ser/Thr GlcNAcβ1-3	
Core 5	GalNAcα-*O*-Ser/Thr GalNAcα1-3	
Core 6	GalNAcα-*O*-Ser/Thr GlcNAcβ1-6	
Core 7	GalNAcα-*O*-Ser/Thr GalNAcα1-6	
Core 8	GalNAcα-*O*-Ser/Thr Galα1-3	
Backbone (elongation) units		
Type 1	Galβ1-3GlcNAc	
Type 2	Galβ1-4GlcNAc	*N*-acetyllactosamine
Poly *N*-acetyl lactosamine type 2	(Galβ1-4GlcNAcβ1-3-)$_n$	i antigen
Branched *N*-acetyl lactosamine type 2	Galβ1-4GlcNAcβ1-6 Galβ1 Galβ1-4GlcNAcβ1-3	I antigen
Peripheral nonreducing termini		
Blood group H type 1 (Galβ1-3GlcNAc)	Fucα1-2Galβ1-3GlcNAcβ1-	Blood group H antigen
Blood group A type 2 (Galβ1-4GlcNAc)	GalNAcα1-3Galβ1-4GlcNAcβ1- |α1-2 Fuc	Blood group A antigen
Blood group B type 1 (Galβ1-3GlcNAc)	Gal α1-3Galβ1-3GlcNAcβ1- |α1-2 Fuc	Blood group B antigen
Sialyl Lewis[a]	Neu5Acα2-3Galβ1-3GlcNAcβ1- |α1-4 Fuc	Sialyl Lewis[a] antigen
Sialyl Lewis[x]	Neu5Acα2-3Galβ1-4GlcNAcβ1- |α1-3 Fuc	Sialyl Lewis[x] antigen
Sulfo Lewis[a]	SO^{3-}3 Galβ1-3GlcNAcβ1- |α1-4 Fuc-	Sulfo Lewis[a] antigen
Sialyl-Tn	Neu5Acα2-6GalNAc-alpha-*O*-Ser/Thr	Sialyl-Tn antigen
Sialyl-T-antigen	Neu5Acα2-3Galβ1-3GalNAcα*O*-Ser/Thr Neu5Ac |α2-6 Galβ1-3GalNAcα*O*-Ser/Thr	Sialyl T or sialyl Core 1 antigen

Ser: serine, Thr: threonine, Neu5Ac: sialic acid, GalNAc: *N*-acetylgalactosamine, GlcNAc: *N*-acetylglucosamine, Fuc: Fucose.
α, β, and numbers indicate the glycosidic linkage between neighboring monosaccharides.

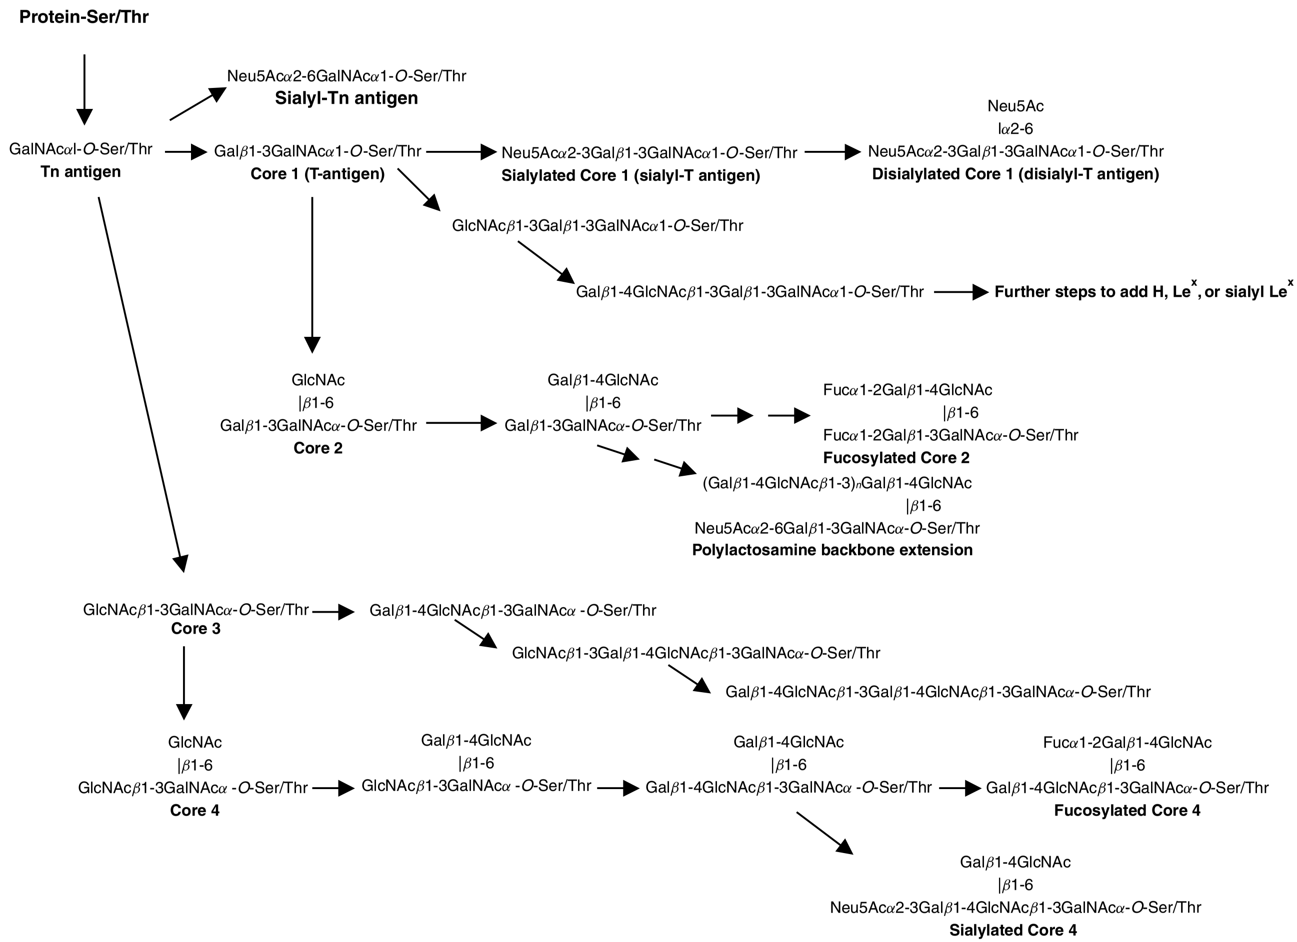

Figure 1 Pathways of Cores 1–4 and extended oligosaccharide biosynthesis. Pathways for the formation of Cores 1–4 and selected examples for their extension. Single arrows indicate the action of one glycosyltransferase, double arrows indicate the action of several enzymes. Ser: serine, Thr: threonine, Neu5Ac: sialic acid, GalNAc: *N*-acetylgalactosamine, GlcNAc: *N*-acetylglucosamine, Fuc: Fucose. α, β, and numbers indicate the glycosidic linkage between neighboring monosaccharides

identified in windows. The windows predict positions for Ser/Thr/Pro, but also exclude certain amino acids including Cys, Trp, Met, and Asp (Gupta *et al*., 1999; Thanka Christlet and Veluraja, 2001).

Second, only those serine and threonine residues that are exposed will be glycosylated. This implies a role for the conformation of the protein, and is confirmed with the identification of *O*-glycans on β-turns and extended structures where proline residues play a role. Furthermore, hydrophobic domains have no *O*-glycans, and bulky amino acids do not feature close to O-glycosylation sites.

Finally, the patterns of O-glycosylation are tissue specific, a function of the initial action of the ppGaNTases and the remaining glycosyltransferases. This has been well demonstrated for the secreted mucin genes where the tandem repeat ser/thr/pro domains contain the same amino acid sequence but where variable glycosylation is found on a tissue specific basis. MUC5AC is expressed in the stomach, respiratory tract, and the conjunctiva, each of which show different glycosylation patterns (Corfield *et al*., 2001). Accordingly, a primary amino acid sequence for *O*-glycan location will not be obvious for this protein.

2.3. Biosynthesis of O-linked glycans

Formation of the *O*-glycans follows a series of biosynthetic pathways that are located in regions of the endoplasmatic reticulum and Golgi apparatus (Van den Steen *et al*., 1998; Brockhausen *et al*., 2001). The primary sequence of oligosaccharides is therefore controlled by substrate specificity of the glycosyltransferases. Initiation of biosynthesis, by addition of GalNAc to serine and threonine residues in acceptor proteins, is mediated by a family of UDP-N-acetylgalactosamine: polypeptide *N*-acetylgalactosaminyltransferases (ppGaNTases) (Ten Hagen *et al*., 2003). These transferases have substrate specificities depending on the location of the serine or threonine residues in the peptide and whether they are already substituted by a GalNAc residue. The enzymes act in a hierarchical manner implying the need for coordinated enzyme action to achieve full O-glycosylation of potential sites. As these enzymes are also expressed in a tissue specific manner, a differential glycosylation pattern will be expected in an organ/tissue dependent manner. The substitution of GalNAc is thus a crucial guiding step in the positioning, level of occupancy, and oligosaccharide extension in defined proteins.

The biosynthesis of the core, backbone, and peripheral regions follows the action of the ppGaNTases to generate the vast library of *O*-glycan structures known. These pathways consist of families of glycosyltransferases, each with a substrate specificity, which defines the characteristic *O*-glycan structures. These enzymes have been reviewed in detail (e.g., (Schachter and Brockhausen, 1992; Brockhausen *et al*., 2001)). To illustrate the action of these enzymes, a pathways map for some of the common core classes and extended oligosaccharide structures is show in Figure 1.

In addition, further modification of some sugars occurs generating new epitopes. The most important of these events are sulfation of Gal and GalNAc (Brockhausen, 2003) and O-acetylation of sialic acids (Corfield *et al*., 1999).

3. The functions of O-linked glycosylation

The functions of *O*-glycans are expected to be wide, ranging in view of the variety of O-glycosylated proteins described. However, only in recent years, clear structure–function relationships have been demonstrated. This section draws attention to the major areas where these interactions have been demonstrated.

3.1. Protein structure and stability

The substitution of an *O*-glycan onto a peptide or protein backbone will have significant influence on the overall structural arrangement of the completely folded molecule. A number of studies have investigated this phenomenon and have shown that many of the properties exhibited are not exclusive but are often shared within one molecule.

3.1.1. Protein conformation, tertiary structure

The mucins and mucin-like molecules with serine threonine proline-rich domains have been used as models to identify changes in protein tertiary structure resulting from O-glycosylation. The addition of the initial GalNAc residue and subsequent elongation of the oligosaccharides results in an extended conformation often referred to as the "bottle brush" structure. A series of investigations on the characteristic tandem repeat sequences found in the MUC genes, in particular MUC1, have demonstrated the modifications to peptide conformation as a result of glycosylation (Otvos and Cudic, 2003). These studies have been correlated with the biosynthetic introduction of the initial GalNAc residues and the specificity of the family of ppGaNAc transferases (Kirnarsky *et al*., 2003). The elegant work of Gerken with porcine submaxillary mucin has shown that the hydroxyamino acid spacing may contribute to the regulation of glycan length, thereby, providing a mechanism for maintaining an optimally expanded mucin conformation (Gerken *et al*., 2002).

Further examples of proteins with "mucin-like" or O-glycosylated "stalk" domains show conformational arrangements that have direct importance in molecular organization, orienting functional/binding domains away from the cell surface. A number of examples exist, including nerve growth factor receptor, CD2, LFA-3, CD8$\alpha\beta$ coreceptor, and calcitonin.

3.1.2. Protein quaternary structure and molecular association

The extended conformations resulting from O-glycosylation offer increased opportunities for molecular interactions at a quaternary level leading to molecular networks and gel structures (McMaster *et al*., 1999). These have been demonstrated typically for the epithelial secreted mucins that have physiological function in adherent gels at mucosal surfaces. In contrast, the prevention of molecular association or aggregation and, therefore, regulation of molecular function can be achieved

through O-glycosylation. This has been demonstrated for lactase phlorizin, secretory IgA, and CD45 dimerization (Van den Steen *et al*., 1998; Xu and Weiss, 2002).

3.1.3. Protein stability protease and heat resistance

The stability of proteins through O-glycosylation is also reflected in protective roles against proteolytic degradation and thermal disruption. These protective properties are lost or absent if the oligosaccharides are removed or are not present. Decay accelerating factor (CD55) is protected in part against proteolysis by O-glycosylation and this regulates the half-life for its biological activity (Van den Steen *et al*., 1998).

The highly O-glycosylated core of mucus glycoproteins is resistant to proteolytic degradation, and this property has been used to prepare mucin glycopeptides. However, protection of protease sensitive domains may also be achieved by site specific O-glycosylation. Thermal stability of protein has been shown in highly O-glycosylated examples such as the mucins and in glucoamylase. Improved thermostability could be introduced into glucoamlyase using mutants designed to increase O-glycosylation in the already highly O-glycosylated belt region (Liu *et al*., 2000).

3.2. Recognition phenomena

O-glycans play roles in a variety of processes that come under the general heading of recognition. These interactions are often complex and may also involve *N*-glycans (*see* Article 64, **Structure/function of *N*-glycans**, Volume 6) present in the same molecules. Such functions continue to accumulate and are briefly reviewed here.

3.2.1. Cell proliferation and growth

Processes associated with cell growth have been found to be closely linked with O-glycosylation. Three examples illustrate the kind of involvement found. (1) The development of muscle tissues is regulated differentially through the polysialic acid containing and other O-linked glycans found in a muscle-specific domain on neural cell adhesion molecule (NCAM). These domains mediate myoblast fusion and the normal development of muscle (Suzuki *et al*., 2003). (2) The hormone-mediated proliferation of breast cancer cells has been shown to be dependent on the O-glycosylation of human sex hormone-binding globulin (SHBG) for binding to a membrane located receptor. The elimination of *O*-glycans on SHBG prevents the inhibition of estradiol-induced proliferation by this hormone (Raineri *et al*., 2002). (3) Induction of apoptosis by agents that cause endoplasmic reticulum stress lead to O-glycosylation of both β-catenin and the E-cadherin cytoplasmic domain. The cadherin/catenin adhesion complexes are regulated by recycling from the plasma membrane and by proteolysis during apoptosis. O-glycosylation of

newly synthesized E-cadherin blocks cell surface transport, resulting in reduced intercellular adhesion (Zhu *et al*., 2001).

3.2.2. Glycoprotein clearance

The clearance of glycoproteins from the circulation is mediated through several different receptors expressed in hepatic, renal, endothelial, and lymphatic tissues. The recognition and binding of the glycoproteins depends on their glycosylation patterns. The hepatic asialo-glycoprotein receptor binds asialo-*N*-glycans in serum glycoproteins but also *O*-glycans with terminal GalNAc. Related receptors have been identified for the elimination of the glycoprotein hormones and insulin-like growth factor binding proteins (Marinaro *et al*., 2000).

3.2.3. Glycoprotein trafficking

The targeting of proteins within the cell has assumed great importance for many aspects of glycosylation and a number of examples have been described supporting a role for *O*-glycans in trafficking pathways (Huet *et al*., 2003). In polarized cells, specific sorting mechanisms are found in the trans-Golgi network. Apical targeting occurs via apical lipid raft carriers and the targeted glycoproteins have glycans mediating their association with rafts and ensuring transport to the correct location (Huet *et al*., 2003). The details of this system remain controversial.

Cellular targeting to the plasma membrane, regulated by *O*-glycan expression has been shown for an increasing number of molecules (Huet *et al*., 2003) including ceramidase, sucrase/isomaltase, CD44, aminopeptidase N, dipeptidyl peptidase IV, human neurotrophin receptor, and C1qRP/CD93. Exit from the endoplasmic reticulum is also determined in this way for cytochrome b5 and human delta opioid receptor G-protein.

3.2.4. Immunological recognition

The immune process relies on the recognition of foreign proteins to initiate a response that leads to protection. The detection of these non–self structures depends on antibodies and T-cells. Glycosylation has a major influence on both of these immunological systems and is also represented in the form of well-known antigenic structures such as the ABH blood groups (Van den Steen *et al*., 1998; Rudd *et al*., 2001).

The human ABH blood groups (see Table 1) are glycan structures carried on both O-and N-linked oligosaccharides in many glycoproteins. Individuals produce antibodies to the non–self blood groups while remaining tolerant to their own. *O*-glycans also contribute to the epitopes in glycophorin A, responsible for the MN and Miltenberger blood groups.

The antibodies IgA1 and IgD have serine/threonine/proline-rich protein domains in the hinge region between the Fab and Fc regions (Novak *et al*., 2000). These peptide sequences are O-glycosylated with short oligosaccharides based on the

Core 1 Galβ1-3GalNAc disaccharide and are largely sialylated. The function of these domains is related to the conformation and stability of the proteins and thus, represents a specific example of the functions already noted above. In the case of IgA1, resistance to proteolytic attack is an important biological requirement for the secretory form of the antibody, which is the major antibody secreted at mucosal surfaces. The conformation of the glycosylated hinge region confers protection to common proteases (Novak *et al*., 2000). Both IgA1 and IgD have been shown to bind to T-lymphocytes through a cell surface lectin that recognizes the *O*-glycans (Van den Steen *et al*., 1998).

Selection of a peptide by antigen presenting cells takes place through the MHC-II-invariant chain Ii system, leading to the appearance of the MHC-II complex at the cell surface. Subsequently, the peptide is recognized by the T-cell receptor on $CD4^+$ T-lymphocytes. Ii contains *O*-glycans that play a role in the stabilization of the intracellular MHC-II-Ii complex (Rudd *et al*., 2001). As noted earlier, thymocyte CD8$\alpha\beta$ coreceptor stalk O-glycosylation affects MHC-I ligand binding (Moody *et al*., 2001). Core 1 sialic acid in addition to CD8β on mature thymocytes decreases CD8$\alpha\beta$-MHCI avidity by altering CD8$\alpha\beta$ domain–domain association and/or orientation.

The binding of peptides selected for presentation to the MHC complex is affected considerably by glycosylation. Glycosylated peptides are processed and presented, but the presence of glycans can also prevent binding or give rise to molecular mimicry. This has been demonstrated in a number of cases in which the binding to the MHC complex groove occurs with O-glycosylated peptides, which mimic certain amino acid residues in nonglycosylated structures (Van den Steen *et al*., 1998; Rudd *et al*., 2001). Peptides substituted with *O*-GlcNAc (*see* Article 72, **O-linked *N*-acetylglucosamine (*O*-GlcNAc)**, Volume 6) have been found to play a role both in the binding to the MHC complex and in the recognition of MHC complex bound epitopes by the T-cell receptor.

A further role for *O*-glycans in immune cells has been found with the demonstration of an *O*-glycan marker on the surface of effector CD8 T-cells. This *O*-glycan was upregulated on virus-specific CD8 T-cells during the effector phase of the primary cytotoxic T lymphocyte response, showed a strong correlation with the acquisition of effector function, and was downregulated on memory CD8 T-cells (Harrington *et al*., 2000).

The mechanisms responsible for autoimmunity also include molecular mimicry, and examples have been described for O-glycosylated glycoproteins (Van den Steen *et al*., 1998). This applies to the truncated Core 1 disaccharide-related structures arising from glycosidase action in infectious diseases such as pneumonia, glycosylation of hydroxy lysine residues in collagen type II leading to arthritis, and antibodies against GlcNAc in Streptococcus group A specific carbohydrate, that are able to cross-react with a cytokeratin peptide.

3.2.5. Selectin ligands

Considerable interest has been focused on the O-glycosylation of selectin ligands as this area has provided excellent examples of structure–function relationships related to the regulation of leukocyte circulation. The different selectins (P, L, and

E) recognize various protein ligands with serine–threonine-rich domains carrying *O*-glycans (Varki, 1997).

PSGL-1 is the major P-selectin ligand. High-affinity interactions with P-selectin require *O*-glycans with a branched Core-2 structure containing the sialyl Lewis^x antigen (see Table 1 for these structures) or other fucosylated glycans. In addition, the coexpression of sulfated tyrosine residues near the critical *O*-glycan structures is necessary (Leppanen *et al*., 2002).

L-selectin mediates tethering and rolling of lymphocytes on high endothelial venules in secondary lymphoid organs binding with specific ligands. The major ligands identified are CD34, GlyCAM, MadCAM-1, podocalyxin, and human endomucin. Recognition by L-selectin depends on peripheral sulfo, sialyl Lewis^x units with Gal-6- or GlcNAc-6-sulfate carried on *O*-glycans. The sulfotransferases generating these sulfated *O*-glycans on L-selectin ligands have been identified and support the structural studies for L-selectin binding requirements (Bruehl *et al*., 2000).

E-selectin, expressed on endothelial cells, mediates adhesion of leukocytes and tumor cells to endothelium. E-selectin ligands have proved more difficult to identify but include PSGL-1, MUC1, and several cancer derived mucin molecules. The ligands also show a requirement for sialyl Lewis^x or sialyl Lewis^a units carried on *O*-glycans, but do not appear to need sulfate for recognition.

There is currently great interest in the regulation of selectin binding through the expression of soluble sialyl Lewis^x substituted glycoproteins during inflammation and disease-related events. In addition, a role for selectin ligands in metastasis has been described focused on cellular mucins carrying sialyl Lewis structures (Varki and Varki, 2001).

3.2.6. Multivalent and multimeric binding and signal transduction

The binding of ligands to receptors can be substantially amplified through interactions with molecules having a repeat structure. Such multivalent ligands have been described for many receptors. The nature of *O*-glycan substitution in serine–threonine-rich protein domains lends itself to the formation of multivalent glycosylated ligands. Increased strength of binding can also be achieved through receptors with multiple units. The combination of mutivalent ligand and multimeric receptor binding can greatly enhance the sensitivity of such systems. The selectins are good examples of this phenomenon. The binding of CD22 to PSGL-1 through sialyl Lewis^x is enhanced through multiple substitution on the ligand and generates the stronger interactions necessary to enable rolling and arrest of circulating leukocytes in the circulation (Van den Steen *et al*., 1998).

3.2.7. Fertilization

Glycosylation is a vital part of recognition processes involved in fertilization. A role for *O*-glycans has been demonstrated in the structure of the oocyte zona pellucida or mucus barrier where differences in structure are species specific. Considerable evidence supports a role for glycans in the fertilization of the oocyte by spermatozoa. This binding is thought to require the interaction of *O*-glycans

linked to a specific protein, zona pellicuda protein 3 (ZP3) on the oocyte, with egg-binding proteins coating the sperm plasma membrane. Sperm cell binding is dependent on a specific ZP3 domain carrying *O*-glycans with nonreducing terminal α-Gal or β-GlcNAc residues (Dell *et al*., 2003). Spermadhesins have been identified as the binding partners in these interactions and may themselves be regulated through glycosylation, which blocks the normal binding. Similar functional molecules have been identified in different species and which also depend on O-glycosylation for their activity. Binding of the sperm to ZP3 triggers release of glycosidase activity, which destroys the *O*-glycan receptors on other sperm cells and prevents polyspermia.

3.3. Activity of signaling molecules

The direct action of glycosylation on the activity of signaling molecules is largely limited to examples where *N*-glycosylation (*see* Article 64, **Structure/function of *N*-glycans**, Volume 6) or *O*-GlcNAc (*see* Article 72, **O-linked *N*-acetylglucosamine (*O*-GlcNAc)**, Volume 6) glycans have a role. A few examples have been described for cytokine and hormone dependency on *O*-GalNAc-based glycans but these interactions remain unclear and are linked with the sophisticated biosynthesis of the initial glycosyltransfer of GalNAc as noted above. The biological activity of interleukin-5 is decreased if IL-5 is O-glycosylated (Kodoma *et al*., 1993), while the presence of an *O*-glycan in granulocyte colony-stimulating factor increases its activity (Nissen *et al*., 1994). Both of these molecules also share stabilizing properties donated by the addition of the *O*-glycans.

The activity of thyroid stimulating hormone and the thyrotropic action of human chorionic gonadotrophin are reduced by desialylation or loss of their *O*-glycans. These few examples indicate variable roles for O-glycosylation and underline the need to examine the complete range of potential functions of *O*-glycans in any individual glycoprotein.

Specialist Review

GPI anchors

Nigel M. Hooper
University of Leeds, Leeds, UK

1. Introduction

Although the majority of integral membrane proteins are anchored by transmembrane hydrophobic polypeptides, numerous proteins are now known to be anchored in the membrane by a covalently attached glycosyl-phosphatidylinositol (GPI) moiety. This complex glycan structure is attached to the C-terminal amino acid of the mature protein and serves to stably anchor the protein in the outer leaflet of the lipid bilayer (Figure 1). As such, a GPI anchor can be considered as an alternative to a C-terminal hydrophobic transmembrane polypeptide domain, as in type 1 integral membrane proteins. GPI-anchored proteins are present in organisms at most stages of eukaryotic evolution, including protozoa, yeast, slime molds, plants, invertebrates, and vertebrates (McConville and Ferguson, 1993). A diverse range of GPI-anchored proteins have been described, including protozoal surface coat proteins, receptors, adhesion molecules, ectoenzymes, and differentiation antigens. Possibly, the most infamous GPI-anchored protein is the prion protein, the causative agent of the transmissible spongiform encephalopathies such as Creutzfeldt–Jakob disease in humans and mad cow disease (bovine spongiform encephalopathy).

In addition to being found attached to proteins, nonprotein-linked or free GPI structures are also present in cells and appear to be functionally important components in their own right (McConville and Menon, 2000). Particularly in certain protozoan parasites, free GPIs are the major class of glycolipids and are essential for parasite growth and infectivity. For example, GPIs from *Plasmodium falciparum* have the properties of the malarial toxin, and synthetic GPI has been reported as a candidate antitoxic vaccine in a model of malaria (Schofield *et al*., 2002).

2. GPI anchor structure

Structural determination of the GPI anchors on proteins from protozoa, yeast, plants, and mammals has revealed the common core structure: ethanolamine-PO_4-6Manα1-2Manα1-6Manα1-4GlcN$H_2\alpha$1-6*myo*-inositol-1-PO_4-lipid (Figure 1). The ethanolamine is amide-bonded to the α-carboxyl group of the C-terminal amino acid of the mature protein. The conserved core structure may possess a variety

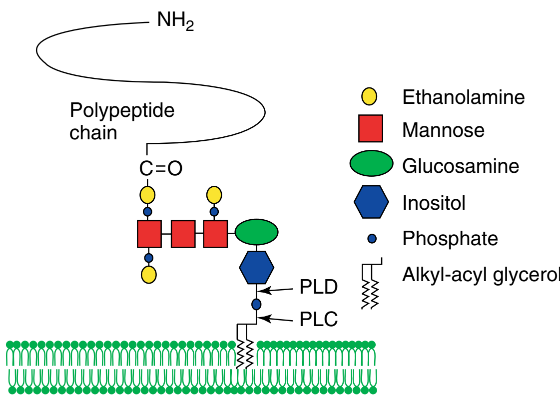

Figure 1 Schematic representation of a GPI anchor. The polypeptide chain is covalently linked through its C-terminus to the core GPI structure ethanolamine-phosphate-(mannose)$_3$-glucosamine-phosphatidylinositol. The lipid, alkyl-acyl-glycerol in the example shown, interacts with the outer leaflet of the lipid bilayer. Additional ethanolamine phosphate groups are shown on the first and third mannose residues. The sites of cleavage by phospholipase D (PLD) and phospholipase C (PLC) are shown on either side of the phosphate within the phosphatidylinositol of the anchor by phospholipase D (PLD) and phospholipase C (PLC) are shown. (Reprinted from *Immunology Today*, **20**, Horejsi V, Drbal K, Cebecauer M, Cerny J, Brdicka T, Angelisova P and Stockinger H, GPI-microdomains: a role in signalling via immunoreceptors, 356–361, (1999), with permission from Elsevier)

of side-chain modifications (additional phosphoethanolamines and sugars e.g., *N*-acetyl-galactosamine, galactose, mannose) that appear to be protein, tissue, or species specific (Brewis *et al*., 1995). The lipid moieties range from ceramide in most yeast and slime mold GPI-anchored proteins to diacylglycerol in protozoa and (predominantly) 1-alkyl-2-acylglycerol in mammalian proteins (*see* Article 77, **Glycosylphosphatidylinositol anchors – a structural perspective**, Volume 6). In some cases, the inositol ring contains an additional lipid modification in the form of an ester-linked palmitic acid (Ferguson, 1992) that renders the anchor resistant to the action of phospholipase C (PLC) (*see* Section 4.1).

3. GPI anchor synthesis and addition

The preformed GPI anchor core is built up by sequential addition of the individual sugars and phosphoethanolamine to a phosphatidylinositol (PI) molecule on the cytoplasmic side of the rough endoplasmic reticulum (ER) (Ferguson, 1999; McConville and Menon, 2000). The process is initiated by the transfer of *N*-acetylglucosamine (GlcNAc) from UDP-GlcNAc to PI, followed by de-N-acetylation of the resulting GlcNAc-PI to give Glc-PI. The Glc-PI is then mannosylated with three mannose residues, each being derived from dolichol-phosphomannose, which in turn is synthesized from GDP-mannose and dolichol phosphate. In mammalian cells and yeast, the Glc-PI must first be acylated on the inositol residue before mannose addition can occur. In other organisms, inositol acylation may occur at a later stage of the biosynthetic pathway. The mannosylated GPIs are then modified with phosphoethanolamine, which is derived

from phosphatidylethanolamine. Most of the enzymes involved in each of these steps have been identified and, to varying extents, characterized (see McConville and Menon, 2000). The completed precursor is then flipped across the membrane into the lumen of the rough ER prior to addition by the transamidase enzyme to a protein with a C-terminal GPI anchor addition signal (see below).

To date, all GPI-anchored proteins are present either on the outer leaflet of the plasma membrane or on an intracellular membrane with the same disposition (i.e., in the lumen of the ER or secretory vesicles). Thus, all GPI-anchored proteins possess two signal sequences in their nascent polypeptide chain (Figure 2a). The first is a hydrophobic cleavable N-terminal signal sequence that is recognized by the signal recognition particle and that cotranslationally directs the protein through the Sec61 translocon complex into the lumen of the rough ER (*see* Article 37, **Signal peptides and protein localization prediction**, Volume 7). The second is another hydrophobic peptide of some 15 to 25 amino acid residues that lies at the very C-terminus of the nascent chain. A hydropathy plot of the nascent (cDNA predicted) amino acid sequence of GPI-anchored proteins clearly reveals these two strongly hydrophobic regions at either end of the polypeptide (Figure 2b). The C-terminal hydrophobic sequence is preceded by a consensus sequence (ω, $\omega + 1$, and $\omega + 2$) for GPI anchor addition (Figure 2a). Cleavage of the polypeptide chain occurs on the C-terminal side of the ω residue, with concomitant addition of the preassembled GPI anchor (see above) to the newly exposed α-carboxyl group of the ω residue by the transamidase enzyme (Figure 3). This transamidase is a

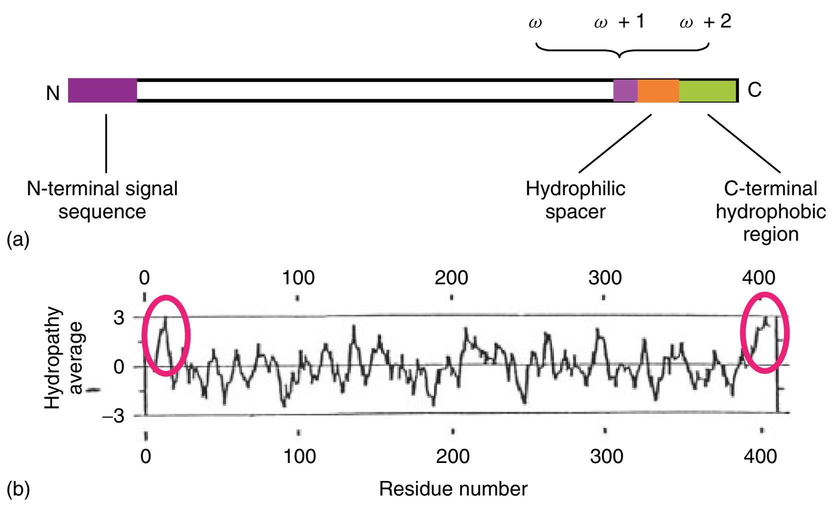

Figure 2 Schematic representation of a typical nascent GPI-anchored protein; (a) the cDNA-derived amino acid sequence of a typical GPI-anchored protein contains an N-terminal signal peptide and a C-terminal signal for directing addition of the GPI anchor. This C-terminal signal consists of a hydrophobic region, a hydrophilic spacer, and three residues ω, $\omega + 1$, and $\omega + 2$. The ω residue is the site of cleavage of the polypeptide chain and of addition of the preformed GPI anchor by the transamidase enzyme (see text for details); (b) hydropathy plot of the nascent polypeptide chain of the GPI-anchored porcine membrane dipeptidase (Rached *et al*., 1990). The strongly hydrophobic regions at the extreme N-terminus and C-terminus are circled

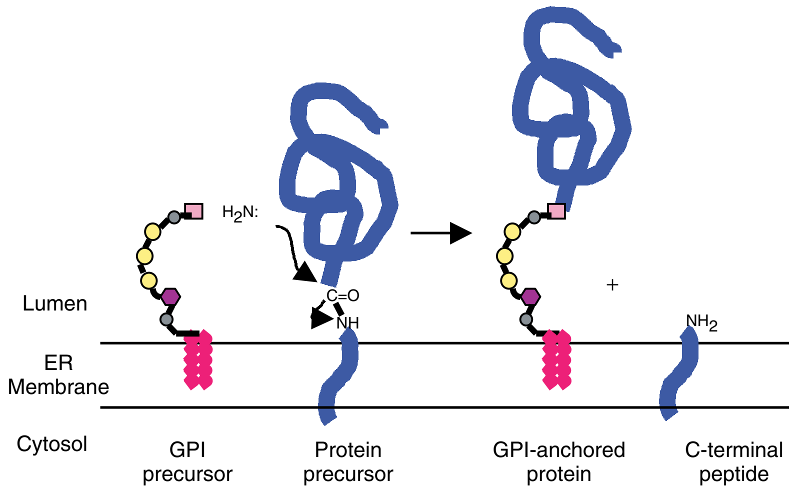

Figure 3 Addition of a GPI anchor to a protein. The C-terminal hydrophobic peptide transiently tethers the nascent polypeptide chain in the membrane of the rough ER following its translation and translocation into the lumen. The GPI anchor is built up by sequential addition of sugars and phosphoethanolamine to phosphatidylinositol (see text for details). The transamidase complex then cleaves the polypeptide chain between the ω and $\omega + 1$ residues (see Figure 2a) and concomitantly adds on the preformed GPI anchor. The released C-terminal peptide is degraded

complex of several proteins, including Gpi8p, which contains the active site of the enzyme, Gaa1p, Gpi16p (PIG-T), and Gpi17p (PIG-S) (Fraering *et al*., 2001). Once added to the protein, addition of other sugars to the core GPI structure may occur as the protein is trafficked through the ER and Golgi.

Analysis of native GPI-anchored protein sequences and extensive site-directed mutagenesis of these residues in the GPI-anchored proteins alkaline phosphatase and decay-accelerating factor (Udenfriend and Kodukula, 1995) has shown that the ω residue is restricted to amino acids with small side chains (Ala, Asn, Asp, Cys, Gly, or Ser), whereas $\omega + 1$ can be any residue except for Pro and Trp and $\omega + 2$ is usually Gly or Ala, or occasionally Ser or Thr. The potential for a protein to be GPI anchored, as well as the most probable site of GPI anchor attachment in the protein, can now be predicted in a manner analogous to the prediction of the site of signal peptidase cleavage at the N-terminus of a protein, using web-based algorithms such as the "big-Π predictor" (available at **http://mendel.imp.univie.ac.at/gpi/gpi_prediction.html** or via **http://ca.expasy.org/tools/**).

4. Identification of a GPI anchor

Although the potential for a protein to be GPI anchored can be predicted from analysis of its cDNA-derived amino acid sequence (see above), the presence of such an anchor structure can only be verified experimentally. The identification of a GPI anchor on a protein does not have to rely upon direct structural determination of the anchor using biophysical techniques such as mass spectroscopy, which require relatively large amounts of highly purified protein and access to such equipment.

Techniques exist whereby the presence of such a structure can be determined even if the protein is present in low abundance or is not readily purified (see Hooper and McIlhinney, 1999; Hooper, 2001).

4.1. Release by bacterial phosphatidylinositol-specific phospholipase C

The susceptibility of a protein to be released from the membrane by bacterial phosphatidylinositol-specific phospholipase C (PI-PLC) is probably the simplest and most commonly used criterion to demonstrate the presence of a GPI anchor. PI-PLCs from *Bacillus thuringiensis* and *B. cereus* are available commercially. Membranes or cells containing the protein of interest are incubated with bacterial PI-PLC and the loss of the protein from the membrane and/or its appearance in the supernatant is monitored following centrifugation (Brewis *et al*., 1994). Alternatively, following incubation with PI-PLC, the membrane sample can be subjected to temperature-induced phase separation in Triton X-114 to separate the intact amphipathic protein from the cleaved hydrophilic form that lacks the fatty acids (Bordier, 1981; Hooper and Bashir, 1991). The lack of release of a protein by PI-PLC does not necessarily rule out the presence of a GPI anchor. Several GPI-anchored proteins are resistant to the action of PI-PLC due to additional acylation of the inositol ring (Ferguson, 1992). However, removal of this acyl group by alkaline hydroxylamine treatment then renders the protein susceptible to cleavage by PI-PLC (Hooper, 2001).

4.2. Detection of the cross-reacting determinant

Polyclonal antisera raised in rabbits against the PLC-cleaved soluble form of one GPI-anchored protein often cross-react with other unrelated GPI-anchored proteins. The site of cross-reactivity is the cross-reacting determinant (CRD), which is cryptic in the membrane-bound amphipathic form of GPI-anchored proteins and is only exposed after cleavage of the GPI anchor with PLC. The major epitope involved in this recognition is the inositol 1,2-cyclic monophosphate that is generated on PLC cleavage of the GPI anchor (Zamze *et al*., 1988; Hooper *et al*., 1991). Thus, the recognition of a protein by an antiCRD antiserum following PLC cleavage is virtually unequivocal evidence for the presence of a GPI anchor.

4.3. Metabolic labeling

If the protein of interest can be expressed in a suitable cell line, then metabolic labeling with components of the GPI anchor can be used to detect the presence of a GPI anchor. The most widely used substrate for labeling GPI anchors is [^{3}H] or [^{14}C] ethanolamine, although other components such as inositol or fatty acids can be used (Hooper and McIlhinney, 1999; Hooper, 2001). Following an appropriate labeling period, the cells are harvested and the protein of interest

immunoprecipitated following either PI-PLC release or detergent solubilization of the membranes. The presence of the radiolabel in the protein can then be assessed by SDS-PAGE followed by fluorography. When using a radiolabelled fatty acid, treatment with PI-PLC or nitrous acid (Hooper, 2001) should be performed to confirm that the fatty acid is in a GPI anchor and not some other lipid modification.

4.4. Detergent insolubility

GPI-anchored proteins, particularly those in mammalian cells, are relatively resistant to solubilization by certain detergents, such as Triton X-100 at 4°C (Hooper and Turner, 1988). In contrast, they are readily solubilized by detergents such as *n*-octyl-β-D-glucopyranoside. This detergent insolubility is an intrinsic property of the GPI anchor due to its clustering in glycosphingolipid- and cholesterol-rich membrane microdomains, so-called lipid rafts (see Section 5.2) (Brown and Rose, 1992). Indeed, the most commonly used method for the biochemical isolation of lipid rafts exploits this insolubility in detergents such as Triton X-100 (Hooper, 2001). Although a few transmembrane polypeptide-anchored proteins are present in lipid rafts, the majority are excluded from such domains and are effectively solubilized from the membrane with Triton X-100 at 4°C. Thus, the relative insolubility in certain detergents can be used to predict the presence of a GPI anchor on a protein.

5. Functions and properties of GPI anchors

The basic function of a GPI anchor is to stably attach the protein to the membrane; however, such a structure can convey additional properties on the protein that may modulate its function.

5.1. Cleavage by phospholipases

In addition to the bacterial PI-PLCs that are routinely used to experimentally demonstrate the presence of a GPI anchor on a protein (see Section 4.1), endogenous phospholipases exist that can cleave the GPI anchor in situ. Such cleavage may be a mechanism for generating a soluble form of the protein whose properties are either the same as or subtly different from that of the membrane-bound form and/or be a means of downregulating the surface expression of the protein. A GPI-specific phospholipase D (PLD) is present in blood plasma that can cleave GPI anchors in vitro, although its role in vivo remains unclear (Low and Huang, 1991). Although several mammalian GPI-anchored proteins have been shown to exist in a soluble form and possess the CRD indicative of cleavage by a PLC (Movahedi and Hooper, 1997; Park *et al*., 2002), to date, this enzyme has not been identified or isolated.

5.2. Association with lipid rafts

Within the plasma membrane of mammalian cells are domains enriched in sphingomyelin, glycosphingolipids, and cholesterol that have been termed lipid

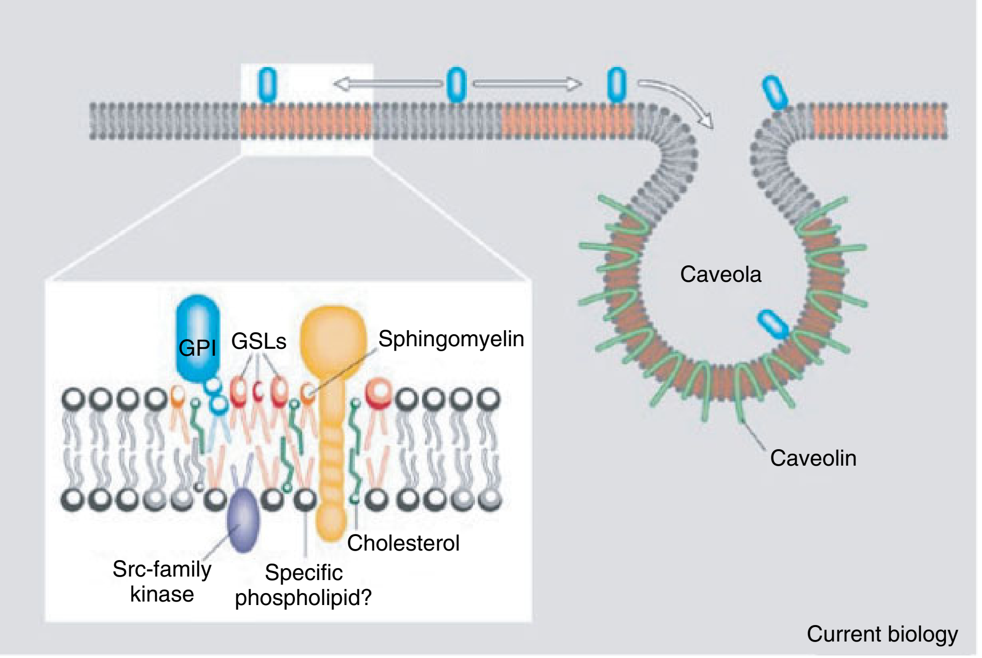

Figure 4 A model for the organization of lipid rafts and caveolae in the membrane. Lipid rafts (red) segregate from the other regions (gray) of the bilayer. The lipid bilayer in rafts is asymmetric, with sphingomyelin (orange) and glycosphingolipids (GSLs; red) enriched in the outer leaflet. Cholesterol (dark green) is present in both leaflets. GPI-anchored proteins (blue) are attached to the outer leaflet of the bilayer, and acylated proteins, such as Src-family nonreceptor tyrosine kinases (purple), are integrated into the cytoplasmic leaflet. Some transmembrane polypeptide-anchored proteins (yellow) are also associated with rafts. Caveolae, with their coat protein caveolin (light green) are subsets of rafts possibly involved in endocytosis. Individual proteins and lipids may move both within and between different rafts. (Reprinted from *Current Biology*, **8**, Hooper NM, Do glycolipid microdomains really exist? R114–R116, (1988), with permission from Elsevier)

rafts (Figure 4) (Simons and Ikonen, 1997; Simons and Toomre, 2000). Owing to intrinsic hydrophobic interactions between the saturated acyl chains of the GPI anchor and the surrounding lipids, as well as interactions between the glycan portion of the anchor and the head groups of the glycosphingolipids, GPI-anchored proteins cluster within these lipid rafts. Recent data show that the two GPI-anchored proteins Thy-1 and the prion protein occupy different, albeit closely adjacent, domains in the plasma membrane (Madore *et al*., 1999) and it is becoming evident that rafts in cells appear to be heterogeneous both in terms of their protein and their lipid content (Pike, 2004).

5.3. *Intracellular targeting signal*

The presence of a GPI anchor often, but not always, causes the intracellular targeting of the protein to the apical surface of polarized epithelial cells (such as intestinal or kidney cells) and to the axonal surface of neurons (Ikonen, 2001).

The association of GPI-anchored proteins with lipid rafts as the proteins and lipids are sorted in the Golgi apparatus may underlie this polarized targeting.

5.4. Transmembrane signaling

Although GPI anchors have no cytoplasmic domain, they can often affect transmembrane signaling. Cross-linking of GPI-anchored proteins with antibodies can mediate an intracellular response, such as a rise in intracellular Ca^{2+}, tyrosine phosphorylation, proliferation, and cytokine induction (Horejsi *et al*., 1999; Ilangumaran *et al*., 2000). The localization of the GPI-anchored proteins in lipid rafts appears to be critical for this function and almost certainly is related to the fact that the cytoplasmic leaflet of lipid rafts is enriched in numerous signaling proteins, such as nonreceptor tyrosine kinases (Figure 4). However, the molecular mechanism by which the signal is passed across the membrane has still to be elucidated.

5.5. Endocytosis via caveolae

GPI-anchored proteins are generally excluded from the classical clathrin-mediated endocytic pathway. Instead, some GPI-anchored proteins, for example the folate receptor, are endocytosed through another structure termed *caveolae* (Nichols, 2003). Caveolae are flask-shaped invaginations of the plasma membrane that contain the coat protein caveolin (Figure 4). Caveolae are also enriched in cholesterol and glycosphingolipids and are insoluble in certain detergents at low temperature and probably represent a subpopulation of the detergent-insoluble lipid rafts.

5.6. Lateral mobility

GPI-anchored proteins lack a cytoplasmic domain and therefore cannot interact directly with the cytoskeleton inside the cell, leading to the assumption that such proteins would be more laterally mobile in the plane of the bilayer. However, the clustering of GPI-anchored proteins in lipid rafts would restrict their lateral movement. Experimentally, some GPI-anchored proteins appear to move more rapidly in the plane of the bilayer (Ishihara *et al*., 1987), while others display a restricted pattern of movement (Zhang *et al*., 1991), indicating that the lateral mobility of any one GPI-anchored protein probably depends on its particular membrane environment.

5.7. Intercellular transfer

Several GPI-anchored proteins have been shown to be transferred from the surface of one cell to another, a phenomenon referred to as *cell painting* (Kooyman *et al*., 1995; Anderson *et al*., 1996). The lack of a cytoplasmic domain certainly is the key to this process and it is known that purified GPI-anchored proteins can spontaneously insert into lipid bilayers. The physiological significance of this process is not clear, but it may enable a particular cell type that does not normally synthesize a particular protein or a cell with limited or no biosynthetic capacity

(e.g., erythrocytes and spermatozoa) to express the GPI-anchored protein on its cell surface under particular circumstances.

Specialist Review

Glycosylation and hepatacellular carcinoma

Anand Mehta
Drexel University College of Medicine, Doylestown, PA, US

1. Hepatocellular carcinoma

Hepatocellular carcinoma (HCC) is a cancer arising from the liver and is referred to as primary liver cancer. HCC is the fifth most common cancer in the world and is the third leading cancer killer worldwide (Block *et al*., 2003). Indeed, liver cancer kills almost all patients who have it within a year. The World Health Organization (WHO) estimated that in 2005 there were 560 000 new cases of liver cancer worldwide, and a similar number of patients died as a result of this disease (**http://www.who.int/en**). The low survival rates have been attributed to the late diagnosis and poor therapeutic options (Di Bisceglie *et al*., 1998).

The frequency of liver cancer in southeast and east Asia and sub-Saharan Africa is greater than 20 cases per 100 000 people. In contrast, the frequency of liver cancer in North America and western Europe is much lower; less than 5 per 100 000 people (Parkin, 2006). However, recent data show that the frequency and mortality of liver cancer in the United States is rising. This increase is primarily due to the chronic infection of hepatitis C virus (HCV), an infection of the liver that leads to cirrhosis and HCC (Marrero, 2006).

HCC is characterized by its propensity for vascular invasion, and microscopic venous or macroscopic portal vein invasion are recorded as being the most significant risk factors for recurrence. Indeed, both intrahepatic metastasis and/or multicentric occurrence contribute to the recurrence in the liver remnant as does an initial large tumor size (especially >5 cm). Even after liver transplantation, often viewed as a cure for HCC, intrahepatic tumor recurrence occurs and is especially frequent in tumors >3 cm (Brechot *et al*., 2000). Although the cause of the tumor (viral infection, alcohol etc.) does not appear to be a significant risk factor for recurrence, there are reports of lower rates of recurrence in hepatitis B virus (HBV)-infected individuals compared to HCV patients (Ichikawa *et al*., 1997; Kumada *et al*., 1997).

2. Risk factor for HCC: hepatitis

Infection with HBV and/or HCV is the major etiology of HCC (Benvegnu *et al*., 1994; Brechot, 1996; Hoofnagle, 1999). Both HBV and HCV can

cause chronic infections of the liver and most chronically infected individuals remain asymptomatic for many years and the clinical disease is not apparent until decades later. Nearly 25–40% of all chronic carriers of HBV or HCV eventually develop untreatable liver cancer (Costello, 1999). Indeed, HBV infection is associated with over 80% of all HCC cases worldwide and can be as high as 96% in regions where HBV is endemic (Beasley, 1988). More than 350 million people worldwide are chronically infected with HBV, including 1.25 million in the United States (Hoofnagle, 1997). HCV is estimated to chronically infect 170 million people worldwide, with 4 million in the United States. With 140 000–320 000 new cases of HBV/HCV reported in the United States each year, the *at-risk* population for HCC has been consistently rising.

The progression of liver disease in asymptomatic chronic carriers of HBV and HCV is monitored by serum liver function tests (LFTs) and ultrasound imaging for the detection of small masses in the liver (Marrero, 2006). Many of the constituents of the LFT panel, for example, transaminase levels, vary throughout the course of chronic hepatitis and are of limited use in the early detection of HCC. Ultrasound detection requires at least a 3-cm tumor mass to be present, and often occurs at a stage at which the prognosis is very poor (Brechot, 1987; Hoofnagle, 1997). Since early surgical and chemotherapeutic intervention is the best hope for patient survival (Brechot, 1987; Di Bisceglie *et al*., 1998), early detection of HCC is necessary to identify the need for intervention. Thus, with a highly defined risk population, the potential for a significant impact on the disease is present.

2.1. Protein glycosylation

The attachment of oligosaccharides to proteins, referred to as glycosylation, is a common co- and posttranslational modification that profoundly affects the biological function of proteins (Varki, 1993). There are a multitude of different types of glycosylation; however, the focus of this article is centered on common glycosylation types associated with proteins that pass through the secretory pathway. The biosynthesis of the oligosaccharide part of the glycoprotein is not genetically encoded, in contrast to the amino acid backbone of the protein. Therefore, information about these biologically important glycan structures cannot be directly gained by a genetic approach. In addition, although the same enzymatic glycosylation machinery is available to all proteins that enter the secretory pathway in a given cell, most glycoproteins emerge with a characteristic (conserved) but potentially heterogeneous glycosylation pattern. Therefore, each protein's glycosylation "profile" is a necessary parameter required for complete protein evaluation in any proteomic study.

The majority of proteins that pass through the secretory pathway are glycoproteins (Monteuil *et al*., 1995) and, consequently, the majority of cell surface proteins are glycosylated (Gahmberg and Tolvanen, 1996). Glycans can be attached to proteins via a variety of linkages and mechanisms. The most common types of glycosylation for cell surface and secreted molecules are asparagine (N-) and

oxygen (O-) linked glycosylation. N-glycosylation is defined by the addition of a preassembled oligosaccharide by the oligosaccharyltransferase (OST) to the side chain nitrogen of an asparagine residue located within a primary sequence signal motif (Asn-X-Ser/Thr, where X can be any amino acid except proline). The presence of this sequon is required for N-glycosylation, but not all sequons are occupied. The transfer of the tetradecasaccharide occurs cotranslationally in the rough endoplasmic reticulum (RER). The oligosaccharide can be involved in RER protein folding (Ou *et al*., 1993; Hammond *et al*., 1994) before undergoing remodeling prior to delivery to the target destination. The extent of remodeling, carried out by a series of competing enzymatic reactions throughout the ER and Golgi apparatus, gives rise to the different classes of N-glycans: oligomannose (least remodeling), hybrid (intermediate), and complex (full remodeling) (Kornfeld and Kornfeld, 1985). Although all N-glycans retain a common pentasaccharide core structure, diversity is potentially huge, for example, the cell surface molecule CD59 contains over 100 different oligosaccharides attached to its single N-glycosylation site (Rudd *et al*., 1997). Mucin-like O-glycosylation is initiated by the transfer of a single monosaccharide (GalNAc) and elongation leads to potentially more complex structures due to the absence of a single conserved core structure. There is a family of transferases which catalyze the initial GalNAc transfer (Clausen and Bennett, 1996; Bennett *et al*., 1998), each member with different specificity (Wandall *et al*., 1997; Hassan *et al*., 2000), consequently, no single O-glycosylation sequon emerges, although certain rules emerge following the evaluation of the enzyme family members.

3. Ubiquity of glycosylation and changes in cancer and development

An investigation of the SWISS-PROT database has shown that almost two thirds of all proteins contain the N-glycosylation sequon, NXS/T, and these may be glycoproteins (Apweiler *et al*., 1999). Assessing the probability of the occupancy of the sequon, it was concluded that half of all proteins are glycoproteins. The number of potential O-glycosylation sites cannot be accurately assessed; therefore, the true number of glycoproteins could be even greater than is currently believed.

Presently, less than 10% of proteins present in the databases are recorded as glycoproteins and even fewer ($<$0.01%) have been well characterized. These figures reflect the fact that accurate and reliable detection, quantification, and characterization of oligosaccharides has been technically very difficult and time consuming. This is unfortunate since alteration in the oligosaccharides associated with glycoproteins, in particular, at the cell surface, is one of the many molecular changes that accompany malignant transformations (Hakomori, 1996; Kobata, 1998). For example, it is well established that in HCC there is an elevation in the amount of fucosylated (Fc) oligosaccharides associated with the secreted α-feto protein (AFP) and is due to, in part, an abnormal secretion system (Miyoshi *et al*., 1999), and other secreted proteins have been shown to be aberrantly glycosylated

(Leray *et al*., 1989; Yamashita *et al*., 1989; Aoyagi, 1995). Cell surface proteins have yet to be evaluated in this system. In addition, there are many examples of abnormal O-glycosylation in cancers of the gastrointestinal tract, pancreas, ovaries, breast, and lung (Brockhausen, 1999; Brockhausen, 2000).

4. Evidence of molecular changes associated with hepatocellular carcinoma

The literature reports many biomolecular changes that occur during the development of HCC. These include (but are not limited to) increased serum activin-A (Pirisi *et al*., 2000), decreased serum retinol levels (Newsome *et al*., 2000), expression of cellular ets-1 (Baumann *et al*., 2000); repression of the cell surface marker CD81 (Inoue *et al*., 2001); and numerous changes that can be identified by comparative genomic hybridization (Zondervan *et al*., 2000) or, in hepatoma cell lines, by complementary DNA (cDNA) microarray analysis (Kawai *et al*., 2001; Patil *et al*., 2005). However, by far the most useful change associated with HCC is the increase in serum AFP (Tatarinov, 1963). AFP is an oncofetal glycoprotein that is (hypothesized to be) produced by transformed liver cells after the development of HCC. However, AFP can be produced under many circumstances, including other liver diseases (Alpert *et al*., 1968; Ruoslahti *et al*., 1974; Di Bisceglie and Hoofnagle, 1989), and is not a definitive marker for the development of HCC. Analysis of the regulatory mechanisms of increased AFP synthesis in hepatic injury and in malignant transformations (Sawadaishi *et al*., 1988; Nakabayashi *et al*., 1989) has been unsuccessful in distinguishing elevation of AFP between HCC and chronic liver disease. The detection of AFP is currently one of the methods by which the development of HCC is detected, although the poor sensitivity of this marker has led people to question its true usefulness in the detection of HCC (Bruix and Sherman, 2005).

5. Change in glycosylation associated with HCC

The literature indicates that changes in glycosylation occur during the development of HCC. The most notable change is an increase in the level of core α-1,6-linked fucosylation of AFP (Breborowicz *et al*., 1981; Miyazaki *et al*., 1981). In HCC and in testicular cancer, the glycosylation of AFP shifts from a simple biantennary glycan to an α-1,6-linked core fucosylated biantennary glycan (Figure 1). These changes have been observed by both direct glycan sequencing of AFP and by increased reactivity of AFP with a variety of lectins that preferentially bind to fucose-containing glycan (Johnson *et al*., 2000). The species of AFP that reacts preferentially with the lectin *lens culinaris* (LCH) is referred to as AFP-L3. Several reports have clearly indicated that AFP-L3 is a more specific marker of HCC than the total AFP protein levels (Taketa *et al*., 1985; Taketa *et al*., 1990; Shiraki *et al*.,

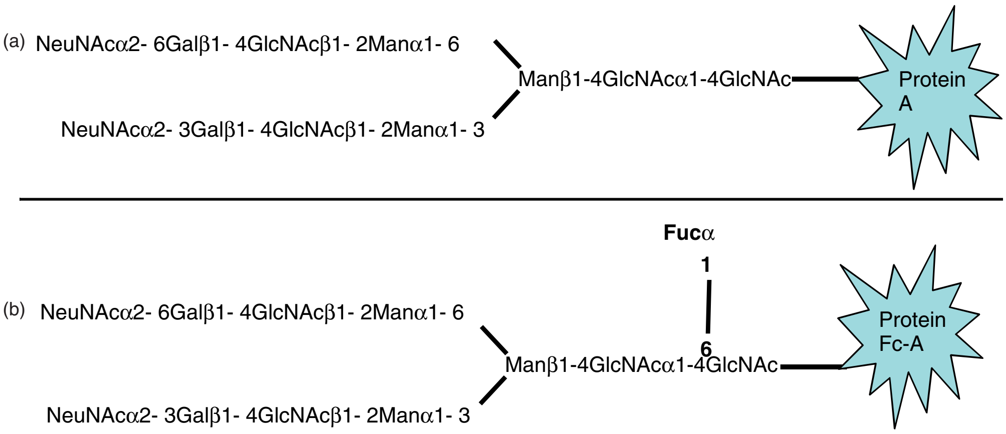

Figure 1 Example of glycoforms. A protein with the exact same amino acid sequence but with a different sugar chain is referred to as a glycoform. Normally, liver cells produce glycoproteins that contain the sugar structure seen in panel A. This is referred to as a biantennary glycan (A2G2). In HCC, the liver cells start to attach a fucose residue to the glycan chain, creating a fucosylated glycoprotein (glycoform, referred to with the Fc prefix). For picture: *N*-acetylglucosamine (GlcNAc); mannose (Man); galactose; (Gal); sialic acid (NeuNAc); fucose (Fuc)

1995). Indeed, AFP-L3 gained approval from the US Food and Drug administration (FDA) in 2005 as the only diagnostic assay for HCC.

In addition to the increases in fucosylation observed on AFP, other changes in N-linked glycosylation have also been observed. These changes include the addition of bisecting *N*-acetylglucosamine (GlcNAc) residues along with increased α-2,6-linked sialation (Morelle *et al*., 2006). These changes have been observed on a more global scale, rather than through the examination of a single glycoprotein.

Although the molecular mechanism of increased fucosylation in HCC is not clear (Noda *et al*., 1998), (Hutchinson *et al*., 1991; Miyoshi *et al*., 1999), it is known that the increase is not restricted to AFP (Yamashita *et al*., 1989; Naitoh *et al*., 1999). Results from several groups have indicated that other liver-derived glycoproteins such as α-1 acid glycoprotein, and α-1 antitrypsin also become fucosylated with the development of HCC, and a recent study has proposed that these glycoforms may be valuable biomarkers of HCC (Naitoh *et al*., 1999). However, a comprehensive comparative analysis of all the fucosylated glycoproteins in HCC patients has not been performed. This type of study has been limited because of the absence of a suitable technology to allow the examination of large pools of unknown proteins. With the advent of sensitive glycan analysis and proteomic technologies, the ability to comprehensively identify all the fucosylated proteins in patients with HCC and to identify these proteins for the development of diagnostic markers is now a possibility.

Recent work has identified global glycan changes that can be observed that correlate with the presence of HCC. This has been performed either on glycan analysis of whole serum (Callewaert *et al*., 2004) or serum that has been depleted of immunoglobulin (Block *et al*., 2005; Comunale *et al*., 2006). In both circumstances, an increase in core fucosylation was observed with the development of HCC. An example of the increase in fucosylation is shown in Figure 2,

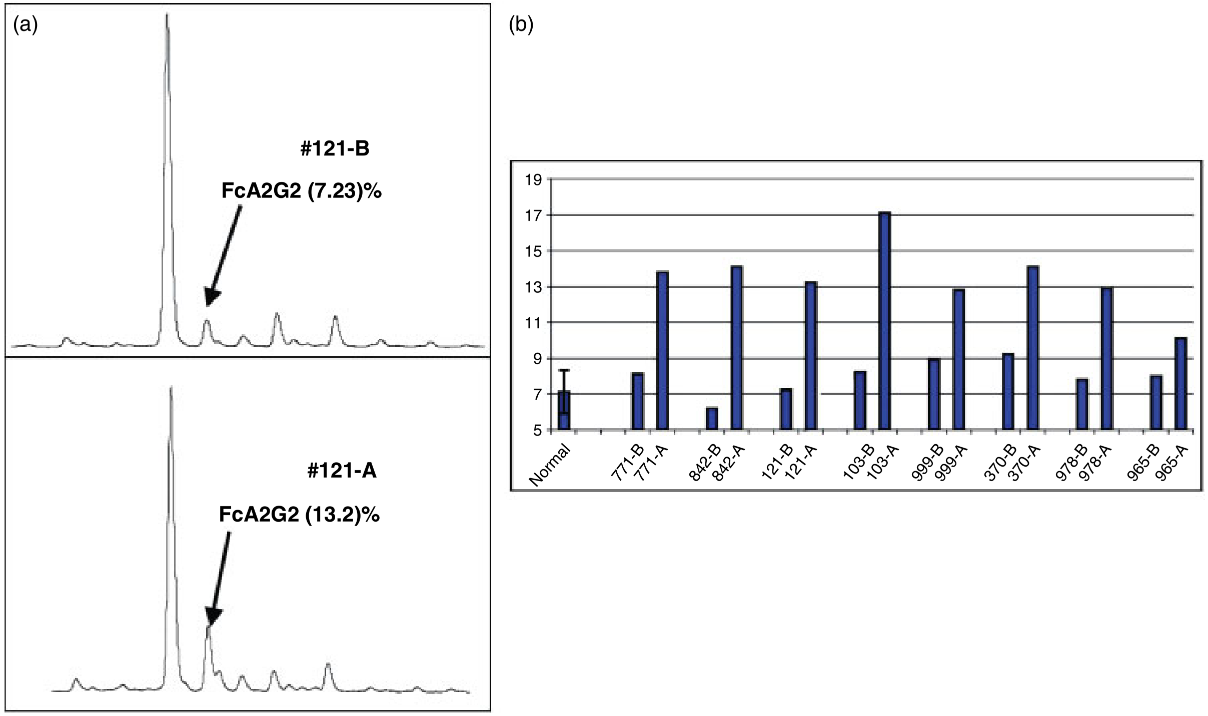

Figure 2 The level of the FcA2G2 glycan in people as a function of time. (a) The level of the FcA2G2 structure in a patient either before (B) or after (A) the diagnosis of cancer as determined by normal phase HPLC analysis (Guile *et al*., 1996). The level of the FcA2G2 structure increases from 7.23% of the total glycan pool to over 13% of the total glycan pool after the diagnosis of cancer. (b) Levels of the FcA2G2 structure in eight individuals either before or after the diagnosis of cancer. For graph, the Y-axis is the percentage of FcA2G2 structure in each individual as a function of total released glycan. The X-axis is the sample number. From Comunale *et al*., 2006

where serum from patients was analyzed by normal phase high performance liquid chromatography (HPLC) (Guile *et al*., 1996; Rudd *et al*., 1999). This small sample set consisted of 16 samples from eight patients at two time points: before the development of cancer or after the diagnosis of cancer. In this case, all patients classified as "before" were clinically diagnosed with cirrhosis (Comunale *et al*., 2006). Samples classified as "after" were clinically diagnosed with HCC by ultrasound and biopsy. As shown in Figure 2, patients before the diagnosis of HCC have much lower levels of the core fucosylated biantennary glycan (FcA2G2) as compared to after the diagnosis of HCC. For example, patient 121 had 7.23% of the FcA2G2 glycan before the diagnosis of HCC and 13.2% after the diagnosis of HCC. As shown in Figure 2(b), this upward trend was true of all patients examined. Consistent with our published results, these results highlight the fact that increased levels of α-1,6-linked core fucosylation are associated with the development of HCC. What was more impressive was that increased levels of core fucosylation were observed in patients that were AFP negative, and we had not been able to make this observation using the conventional screening methods. That is, as shown in figure 2(b), patients 965, 370, 842, 999, and 978 were all AFP negative, yet had increased levels of the FcA2G2 glycan (Comunale *et al*., 2006).

To identify those proteins that had increased fucosylation, the fucosylated glycoproteins associated with sera from either pooled normal or pooled HCC-positive individuals were extracted using fucose-specific lectins and the proteome analyzed by either two-dimensional gel electrophoresis (2DE) or by a simple LC MS/MS–based methodology designed to identify fucosylated peptides (described in Comunale *et al*., 2006). Using these methodologies, it was determined that glycoproteins such as fucosylated α-1-acid glycoprotein, Fc-ceruloplasmin, Fc-α-2-macroglobulin, Fc-hemopexin, Fc-Apo-D, Fc-HBsAg, and Fc-Kininogen increased in patients with HCC, while the levels of Fc-haptoglobin decreased in the these patients (all listed in Figure 3) (Comunale *et al*., 2006). Many of these proteins are acute phase proteins that are secreted by the liver. Although the analysis of a panel of fucosylated proteins as a marker of liver disease has been postulated before (Turner, 1992; Turner, 1995), a comprehensive analysis of the total fucosylated proteome as a function of the disease has not been performed. However, with the current protein chip–based systems, the analysis of a large number of fucosylated proteins can now be used to determine if a fucosylated "biosignature" exists that can be utilized to diagnose the disease.

6. Conclusion

Changes in N-linked glycosylation have long been associated with the development of the disease (Kim and Varki, 1997; Dennis *et al*., 1999; Taylor-Papadimitriou *et al*., 1999; Kellokumpu *et al*., 2002; Peracaula *et al*., 2003). In the case of liver cancer, it has been clearly shown that an increase in core fucosylation is associated with the development of the disease, in both animal models and in people (Breborowicz *et al*., 1981; Miyazaki *et al*., 1981; Taketa *et al*., 1985; Taketa *et al*., 1990; Kelleher *et al*., 1992; Ajdukiewicz *et al*., 1993; Shiraki *et al*., 1995; Block *et al*., 2005; Comunale *et al*., 2006). This finding has led to the only diagnostic

marker of HCC approved by the US Food and Drug Administration. However, for HCC, this may represent just the tip of the iceberg. As many more glycoproteins with altered glycans are identified, a marker that can identify early liver cancer with 100% sensitivity and 100% specificity may soon be at hand.

Specialist Review

Protein glycosylation and renal cancer

Roisean E. Ferguson, Naveen S. Vasudev, Peter J. Selby and Rosamonde E. Banks
Cancer Research UK Clinical Centre, University of Leeds, Leeds, UK

1. Introduction

Cancer is the second most common cause of death in the Western world and was responsible for over 6.2 million deaths in 2000 worldwide (International Agency for Research on Cancer, 2003). It is a disease that poses many challenges to the clinician, including early detection, monitoring of disease progression, predicting patient prognosis, optimization of treatment selection, and monitoring of therapeutic response.

One of the critical factors in the survival from cancer is detection at an early stage, as, with few notable exceptions, survival rates for advanced cancers have remained relatively static over the last 20 years (National Cancer Institute, Surveillance Epidemiology, and End Results program **http://seer.cancer.gov/**). The impact on survival by combining early detection with current therapies would be significant as outcomes generally improve when treatment is applied to a disease that is confined to the tissue of origin. The identification of diagnostic markers for earlier diagnosis coupled with the identification of novel therapeutic targets is central to the future successful treatment of cancer. To this end, an ongoing challenge in cancer research is to identify disease-associated differences between normal and cancer cells so that they might be harnessed for diagnosis and targeted for more selective treatments.

It is well established that cancer development proceeds via a succession of genetic alterations, each providing an advantage that ensures their survival, generally resulting in an insensitivity to anti-growth signals, evasion of apoptosis, sustained angiogenesis, and metastasis (Hanahan and Weinberg, 2000). Ultimately, these genetic mutations are manifest at a protein level, resulting in changes in expression, post-translational modification, activity, and localization, all of which affect cellular function. It is important to characterize the functional consequences of such genetic alterations in terms of protein structure and function to address what changes are involved in the transformation of a normal cell to a malignant one. The identification and understanding of these changes are fundamental to the identification of novel markers and therapeutic targets.

There is abundant evidence to show that malignant transformation is associated with a dramatic alteration of cellular glycosylation (Dennis *et al*., 1999a; Orntoft and Vestergaard, 1999). Since glycosylated proteins (glycoproteins) coat all eukaryotic cells, such changes have effects on carbohydrate recognition mechanisms implicated in cell adhesion and motility as well as intracellular signaling events, enabling tumor development (Kim and Varki, 1997; Dennis *et al*., 1999a). Recent technological advances in the field of glycobiology have shed some light on the functional significance of glycosylation changes, and there is now much research effort to elucidate disease-specific glycans to allow specific targeting and destruction of cancer cells or to employ these glycans for diagnostics (Shriver *et al*., 2004; Dube and Bertozzi, 2005; Fuster and Esko, 2005).

2. Glycans in cancer development

The nature of glycosylation and its role in biological processes is covered elsewhere within this section. There is abundant evidence to suggest that cell surface glycosylation is altered in cancer. Earlier observations noted that the glycoproteins in transformed cells were larger than those found in healthy cells (Meezan *et al*., 1969), and this has been demonstrated many times since. This can reflect altered cellular metabolism, but changes in glycosylation have also been directly associated with tumor development and progression. Examples include the role of glycans in cell–cell recognition, cancer cell metastasis, and homing (Dennis *et al*., 1999a; Orntoft and Vestergaard, 1999; Gorelik *et al*., 2001; Kannagi *et al*., 2004).

A number of common changes in glycosylation occur. Epithelial tumors often overproduce mucin glycoproteins such as MUC1 and CA125 (MUC16), and a number of tumor marker assays currently in use, including CA 125 and CA 19-9, are based on epitopes that are carried on mucins (Hollingsworth and Swanson, 2004). Changes in expression levels of glycosyltransferases in cancer cells lead to the frequent expression of a number of terminal glycans such as sLe^x, sLe^y, sLe^a sialyl-Tn, GloboH, and polysialic acid (for a review, see Hakomori, 2000). A common feature of malignant cells is an increase in size and branching of *N*-glycans, attributed to the increased expression of *N*-acetylglucosaminyltransferase (GnT-V (Dennis *et al*., 1987)). The association between β1-6 branching and tumor progression (Kim and Varki, 1997; Dennis *et al*., 1999a; Dennis *et al*., 1999b; Orntoft and Vestergaard, 1999) explains the observations of the increased size of tumor membrane glycoproteins (Meezan *et al*., 1969). The increased branching produces increased sites for sialic acids, which, in conjunction with upregulation of the sialyltransferases, leads to a global increase in sialylation. Formation of less complex structures in O-linked mucin-type carbohydrate chains is another common change (Kim and Varki, 1997; Orntoft and Vestergaard, 1999). MUC1 is a good example of the latter where it is both upregulated and aberrantly glycosylated in $>90\%$ of breast cancers (Taylor-Papadimitriou *et al*., 2002). Truncation of O-linked glycans leads to the appearance of novel glycan epitopes such as the sialyl-Tn and Thomsen–Friedenreich antigens while simultaneously making the peptide of the protein more exposed. Some cancers exhibit an increased expression of gangliosides such as GM1, GM2, GD2, and GD3 (Hakomori, 2000). In addition,

high levels of hyaluronan, which is a major component of the extracellular matrix, are associated with malignant progression in many cancers including breast and colorectal cancers (Fjeldstad and Kolset, 2005). There are numerous other examples where the carbohydrate phenotype has been an indicator of the malignant potential. In particular, a correlation between the expression of sLe^x and increased branching of *N*-linked glycans and metastatic potential has been demonstrated in a number of studies (Demetriou *et al*., 1995; Granovsky *et al*., 2000). Specific examples of alterations associated with renal cancer are detailed later.

3. Studying the cancer glycoproteome: a potentially rich source of biomarkers and therapeutic targets

Because cancer cell glycans differ from those found in normal healthy cells, it follows that it should be possible to target them specifically on the basis of their altered glycosylation or use the cancer-specific glycans for diagnosis (Dwek and Brooks, 2004). In some cases, glycoproteins produced by the cancer cells may be secreted or released into the blood stream or urine, forming the basis of a diagnostic test for the cancer.

Unlike proteomics and genomics, the field of glycoproteomics has been hindered by the sheer complexity of the macromolecules involved. Progress toward delineating the molecular basis of the glycan function, in particular, has been extremely challenging as it has many roles that depend not only on the protein to which it is attached but also the precise site of attachment, thereby making it necessary to document the structure and function of the glycoprotein as a whole. Glycan synthesis is nontemplate driven, hence it has greater structural diversity than both proteins and nucleic acids and needs to be considered as a heterogeneous mixture of different chemical structures when isolated from cells or tissues. The difficulty in synthesising complex carbohydrates to decipher structure–function correlates has also been a significant challenge.

Several approaches have been undertaken to characterize cancer-associated glycosylation changes. Mass spectrometry, in combination with various chromatographic methodologies, is one of the most powerful and versatile techniques for the structural analysis of oligosaccharides (Tabares *et al*., 2006). The use of monoclonal antibodies against specific glycan structures (Sell, 1990), as well as studying the binding pattern of lectins to the glycoproteins of healthy compared to cancerous tissue sections (Streets *et al*., 1996) or lectin-based blotting of normal and tumor tissue glycoproteins that have been resolved by 1D- or 2D-PAGE, has also been tried (Osborne and Brooks, 2006). Much has been gleaned on the function of particular cellular glycans by perturbation of their synthesis through the use of glycosylation inhibitors or glycosidases, as well as alteration of the glycosyltransferase expression (Bertozzi and Kiessling, 2001; Moremen, 2002; Patsos *et al*., 2005). Genetic knockouts have provided invaluable insight into the importance of particular glycans in tumor progression (Granovsky *et al*., 2000; Lowe and Marth, 2003), and there is now great impetus to decipher disease-specific glycans so that they are targeted to specifically destroy cancer cells that display them or their presence is used for diagnostic means.

3.1. Biomarkers

Currently, a number of circulating tumor-derived glycoproteins such as CA125, prostate-specific antigen (PSA) and carcinoembryonic antigen (CEA) function as tumor markers; however, they suffer from a lack of specificity. Their expression is not unique to cancer cells as they are often raised in a variety of non-malignant conditions and their levels are not always elevated with cancer (Ugrinska *et al*., 2002).

More recently, detailed analysis of the glycan structures of PSA and CA125 proteins has revealed cancer-specific differences, and may ultimately enable further discrimination between cancer and benign disease (Kui-Wong *et al*., 2003; Tabares *et al*., 2006). The glycan changes *per se* that indicate malignancy are already being employed in diagnosis; the commonly used CA19-9 test for pancreatic cancer measures serum levels of sLe^a and currently represents the most specific test for this cancer (Magnani, 2004). Tumor-specific glycosylation may also be analyzed via lectin staining of histological samples; in fact, much of our initial insight into the changes in glycosylation of cancer cells emerged from the differential binding of lectins between healthy and cancerous tissue (Ching *et al*., 1988; Blonski *et al*., 2005). First discovered in the 1880s, lectins are carbohydrate-binding proteins of nonimmunological origin. They have specific but overlapping affinities for particular glycan structures, thus their binding to normal and tumor glycoproteins provides information on the nature of the changes being observed (for a detailed review, see Sharon and Lis, 2004). One lectin, in particular, *Helix pomatia* agglutinin (HPA), has been extensively used in cancer research as an indicator of poor prognosis in breast, lung, colorectal, gastric, and prostate cancer (Mitchell and Schumacher, 1999). More recently, aberrant glycosylation in cancer cells has been employed for molecular imaging to monitor breast cancer in murine tumor models using peptide conjugates that bind to the underglycosylated form of MUC1 (Moore *et al*., 2004).

3.2. Glycotherapeutics

Although it is evident that glycosylation is altered with cancer, dissecting the role of specific glycans has been extremely challenging. This is because cellular heterogeneity is very common during the evolution of neoplasias, but, in addition, the micro heterogeneity of glycosylation presents further problems in correlating the presence of a specific glycans to the biology of a given tumor. Despite this, there are numerous examples where the altered glycosylation has been targeted for therapeutic purposes, some of which are outlined below.

Interactions between circulating tumor cells and remote vascular endothelium are key early events in cancer metastasis. The interaction of selectins on endothelial cells with the carbohydrate determinants, sLe^x and sLe^a, which are commonly overexpressed on cancer cells constitutes an important step in this process (Kannagi *et al*., 2004). Numerous studies have demonstrated that the expression of these antigens is inversely correlated with patient survival (Nakagoe *et al*., 2002; Saito *et al*., 2003). Modification of tumor cell surface antigens with GlcNAc

analogues has been used to reduce tumor cell adhesion (Woynarowska *et al*., 1996) and small molecule mimetics of sLe^x or sLe^a selectin ligands (Dey and Witczak, 2003; Fuster *et al*., 2003) as well as disaccharide decoys that interfere with selectin–carbohydrate interaction have been considered for the treatment of metastatic diseases. Therapies based on the blocking of tumor-associated glycan formation using inhibitors of glycoprocessing enzymes are another possibility. GnT-V is a key enzyme in the formation of branching of *N*-linked oligosaccharides, which is strongly linked to tumor invasion and metastasis of colon and breast cancers (Fernandes *et al*., 1991) and its expression is an independent predictor of superficial bladder cancer recurrence (Takahashi *et al*., 2006); however, currently no such inhibitors are undergoing therapeutic evaluation. Of the carbohydrate-processing inhibitors presently available, the alkaloid swainsonine, a Golgi α-mannosidase II inhibitor, was the first to have been selected for clinical testing based on its anticancer activity. It also exhibited low toxicity in a number of Phase I cancer trials (Fuster and Esko, 2005). Since increased sialylation is associated with metastatic potential, inhibition of the sialyltransferases has also been considered as a therapeutic strategy (Drinnan *et al*., 2003) and inhibition of ST8aII by synthetic sialic acid precursors has been demonstrated *in vitro,* but, as yet, has not been replicated *in vivo* (Horstkorte *et al*., 2004). Several glycan-based vaccines against tumor glycans are presently undergoing clinical trials, with variable success (for a comprehensive review, see Dube and Bertozzi, 2005; Ouerfelli *et al*., 2005), and multiantigenic vaccines are currently undergoing preclinical evaluation (Ragupathi and Livingston, 2002). The use of lectins for targeted drug delivery has recently been demonstrated *in vivo* (Robinson *et al*., 2004).

4. Renal cancer: a challenging malignancy

Renal cancer represents approximately 3% of adult malignancies with a male-to-female ratio of 2:1, causing 102 000 deaths worldwide (Parkin *et al*., 2005). However, the incidence of this cancer is increasing with a 126% increase in incidence since the 1950s in the United States of America (Pantuck *et al*., 2001) and a reported 18% increase in incidence rate in the last 10 years in females in the United Kingdom, which is one of the largest rises in the incidence rate of any cancer in women (Cancer Research UK Cancer Stats, 2005).

Approximately 70% of renal tumors are histologically classified as conventional or clear cell renal cell carcinomas (RCC), thought to arise from the proximal tubule (Pantuck *et al*., 2001). Tumor stage and grade are the most useful prognostic indicators with a 5-year survival of 16–32% for those with metastatic disease (Pantuck *et al*., 2001). Surgical resection of the primary tumor remains the main treatment option for organ-confined disease; however, owing to the relatively asymptomatic nature of the disease, over 50% of patients present with a locally advanced stage of metastatic disease. Their prognosis remains poor since renal cancer is unresponsive to radiotherapy and also represents one of the most chemoresistant of tumors as none of the commonly used cytotoxic agents provide appreciable activity (Motzer and Russo, 2000). More promising response rates have been reported with biological therapies such as interferon and interleukin-2;

however, these are associated with overall response rates of less than 20% (Zhou and Rubin, 2001).

There is a clear need to identify biomarkers for detecting renal cancer while still resectable, as well a need for novel therapeutic targets. There are currently no tumor markers in routine clinical use for detection, staging, or monitoring of renal cancer evolution and treatment. The identification of diagnostic and prognostic markers is thus an intense area of investigation and the National Cancer Institute (NCI) has identified the development of biomarkers and therapeutic strategies for renal cancer as a priority area for research (National Cancer Institute, 2002).

5. Glycosylation and renal cancer: the quest for biomarkers and therapeutic targets

While in recent years much progress has been made in characterizing and understanding the changes in glycosylation that occur in cancer, much of the effort has been focused around the more common cancer types. By comparison, therefore, relatively little is known regarding glycosylation and renal cancer. Although the studies are somewhat limited, it is clear that renal cancer demonstrates an altered pattern of glycosylation compared to the normal kidney.

The majority of the studies examining glycosylation changes in renal cancer are based around descriptive studies of lectin-staining patterns in the normal kidney compared to that in renal cancer tissues. Lectin histochemistry is a useful tool to detect subtle alterations in glycosylation of cancer tissues, and the lectin-staining properties within individual tissues may have relevance to the neoplastic process, as alterations in cell morphology alone may not indicate the underlying malignant potential and patient prognosis. While some detailed studies have been made, comprehensive studies are few and the numbers of specimens evaluated are often very small (in fact, in some cases only one patient has been examined). In the normal adult kidney, particular sugar residues are strictly confined to various parts of the nephron. For example, the binding of the lectin *Lotus tetragonolobus* agglutinin (LTA), specific for α-1-fucose residues, is limited to the proximal convoluted tubule. Others, such as Soybean agglutinin (SBA), Dolichos biflorus (DBA), and Peanut agglutinin (PNA), that bind to α- or β-linked *N*-acetylgalactosamine (and to a lesser extent, galactose residues), *N*-acetyl-α-D-galactosamine, and β-D-galactose, respectively, are restricted to the distal convoluted tubules and collecting ducts (Holthofer *et al*., 1981).

In the malignant kidney, the pattern of lectin staining is consistently reported to be altered; however, there are numerous discrepancies in the changes that are described, hence little consensus can be drawn. This is likely to reflect technical differences in methodologies and also the inherent heterogeneity that is associated with renal cancers. Studies into renal cancer have variably used fluorochrome-labeled lectins, biotinylated lectins, and horseradish peroxidase–coupled lectins to label frozen or paraffin-embedded tissues as well as single cell suspensions. Such variation in methodology can seriously affect the pattern of lectin staining observed and therefore the correlations that are made (Brooks *et al*., 1996). It is apparent

that further complexity is presented with renal cancer, as there is considerable interpatient heterogeneity reported within studies (Raedler *et al*., 1982; Ulrich *et al*., 1985).

Binding of LTA in RCCs has been variably reported as absent, to approximately 60% positivity and as high as 90% in well-differentiated tumors (Holthofer *et al*., 1983; Hanioka *et al*., 1990; Ulrich *et al*., 1985). Lectins that are normally confined to distal convoluted tubule, such as SBA, show positivity rates of between 37.5 and 95% (Iizumi *et al*., 1986; Hanioka *et al*., 1990) and DBA between 0 and 25% (Holthofer *et al*., 1983; Ulrich *et al*., 1985).

Ongoing work within our own laboratory has sought to identify the renal cancer-associated glycoproteins/glycoforms, where the aim is that they may form the basis of novel biomarkers or therapeutic targets. Using a combination of lectin histochemistry on matched normal kidney and cancer tissue specimens, as well as lectin-based blotting of tissue lysates separated by one-dimensional and two-dimensional polyacrylamide gel electrophoresis (PAGE), the binding pattern of a number of lectins has been examined, several of which exhibited alterations in binding between matched tumor and normal tissues. Examples of both tissue lectin histochemistry and lectin blots of tissue glycoproteins are shown in Figure 1.

(a) SNA binding is present in the glomeruli of the normal kidney, but is largely absent from normal tubular epithelial cells. In contrast, strong membranous staining of tumor cell membranes is apparent.

(b) Lectin blot of normal and tumor tissue proteins resolved by 2D PAGE. A number of glycoproteins are present in the tumor only.

These studies help in establishing the aberrant nature of glycan expression in RCCs, but, by themselves, reveal little about specific changes or the role of glycans in renal cancer. Ulrich and colleagues reported a correlation between tumor grade and LTA positivity (with high-grade tumors showing universal absence of binding),

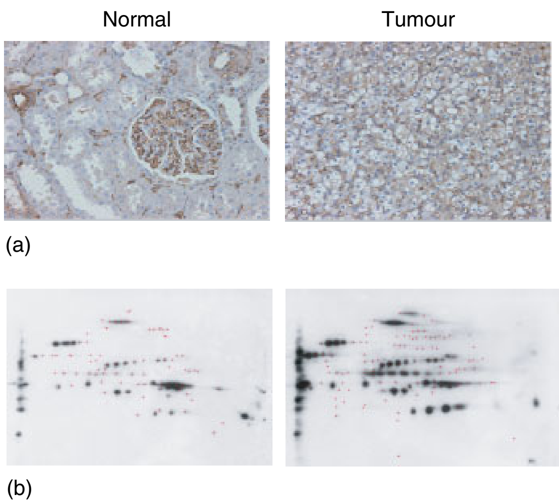

Figure 1 Lectin histochemistry and lectin blotting of matched normal kidney and tumor tissues with *Sambucus nigra* (SNA)

suggesting that well-differentiated low-grade tumors express the carbohydrate components of the tubular cells from which they are supposed to originate with a higher incidence than their more malignant counterparts (Ulrich *et al*., 1985). Like many other tumors, the expression of sLe^x has been correlated with both histological parameters and prognosis in patients with RCC. Immunohistochemistry has shown that tumors with higher levels of expression are associated with higher grade, vascular infiltration, and early relapse (Tozawa *et al*., 2005). One of the molecular mechanisms underlying this overexpression appears to be linked to the switching from oxidative to elevated anaerobic glycolysis (Warburg effect) that tumors often undergo in response to hypoxia. The resultant accumulation of hypoxia inducible transcription factors (HIF) (often also constitutively activated in RCC via loss of the von Hippel Lindau tumor suppressor gene) is thought to lead to the enhancement of glucose transporters and glycosyltransferases related to the sLe^x-determinant expression (Koike *et al*., 2004; Kannagi, 2004).

Galectins are a major class of glycoproteins that bind to ß-galactoside sugars and are involved in cell–cell interactions. Galectins-1 and -3 have been implicated in the progression of various cancers (for a review, see van den Brûle *et al*., 2004). Galectin-3 expression in RCC has been reported as being associated with tumor indolence, being expressed predominantly in low-grade conventional RCCs, indolent chromophobe RCCs, and benign oncocytomas (Young *et al*., 2001). In another study, RCC aggressiveness was related to a decrease in galectin-1 binding sites (and to a lesser extent, galectin-1 expression) and a trend toward decreased galectin-3 binding sites (Francois *et al*., 1999).

Our current understanding of the mechanisms that underlie these changes in surface glycosylation in RCC, and indeed in other cancers, is extremely poor. The most well-characterized enzymes involved in glycan assembly are the *N*-acetylglucosaminyltransferases (GnT), which play a critical role in the antennary number, linkage, and bisecting structure of glycans. They are commonly observed to be overexpressed in many tumors, and, in particular, in GnT-V (Taniguchi *et al*., 2001). In contrast to this, the level of GnT-V activity in RCC has been reported as being almost identical to the normal kidney, and the level of activity of GnT-III and -IV to be considerably reduced (Zhu *et al*., 1997). This finding is further supported by the observation that gamma-glutamyltransferase (GGT) is differentially glycosylated in RCC in comparison to the normal kidney. RCC GGT contained comparatively fewer complex-type bisecting GlcNAc chains, consistent with a reduced expression of GnT-III in RCC (Yoshida *et al*., 1995).

6. Summary and future challenges

Although there has been enormous progress in understanding the mechanisms of cancer development, paralleled advances in cancer treatment have not been forthcoming (Weir *et al*., 2003). Cancer is a highly complex disease, there are many different cancer types, and within each cancer there are different subtypes, which are often associated with different clinical behaviors and outcomes. Earlier detection, as well as the identification of novel therapeutic targets, is essential for the future successful treatment of this disease. This is particularly true for renal cancer, where

early surgical resection of the primary tumor is essential for successful treatment; however, because it is relatively asymptomatic, it is too often diagnosed too late. A major goal of cancer research therefore is to identify diagnostic and prognostic biomarkers that are associated with malignancy from patient tissue, serum, or urine. Protein glycosylation changes dramatically with cancer and glycans are engaged in many aspects of tumor progression; therefore, they represent opportunities for diagnostics and therapeutics.

Changes in glycosylation are apparent in cancer; however, no one change seems to distinctly differentiate normal and malignant tissue, rather each malignancy is characterized by a set of changes in glycan expression. Hence, combinations of changes, a "glycan signature" of the disease, may be most informative. So far in the clinic, altered glycosylation has been harnessed mainly for biomarkers due to the secretion of tumor-derived glycoproteins into the bloodstream or into other bodily fluids, and it is important that this continues and further discoveries are exploited. The current effort is now directed at understanding the role of glycosylation in cancer, and the possibilities of manipulating glycan function to minimize processes such as metastasis and increasing immune response toward cancer cells are currently being explored. Glycoproteomics is a relatively new field and important breakthroughs in glycobiology fueled by rapid technology advances have resulted in a renaissance in the past few years. It is an overwhelming task to elucidate precise mechanistic functions for each type of aberrant glycosylation seen with cancer. However, the potential gain for diagnosis and therapeutics justifies perseverance in this difficult and complex field of research. To advance this burgeoning field, several international collaborative efforts, such as the Consortium for Functional Glycomics, an international initiative funded by the National Institute of General Medical Sciences, have been established (Raman *et al*., 2006) and the progress described so far is likely only to be the very tip of the iceberg.

Short Specialist Review

Posttranslational cleavage of cell-surface receptors

Martin Stacey, John Davies, Siamon Gordon and Hsi-Hsien Lin
Sir William Dunn School of Pathology, Oxford, UK

1. Introduction

In eukaryotic cells, nascent polypeptides generated by ribosomes rarely represent the true form of mature proteins. Instead, many newly synthesized proteins undergo posttranslational modifications that may mediate either subtle or profound effects on the function of the protein. Once translated, peptides may be altered by the covalent modification of either side chains or terminal amino acids through a variety of enzymatic processes. These include phosphorylation, deamination, hydroxylation, ubiquitination, prenylation, glycosylation, acylation, and methylation. Peptide bond formation may even occur between the side groups of different peptides via an isopeptide bond. Isopeptide formations are mediated by transglutaminases that catalyze the cross-linking of different proteins via ε-(γ-glutamyl)lysine bonds. Proteolytic cleavage differs from the above mechanisms of posttranslational modification in that it is irreversible. Site-specific proteolysis plays an important role in a diverse range of biological processes such as the proenzyme and hormone activation, determination of cell fate, release of cell-associated growth factors, protein trafficking, tissue remodeling, and apoptosis. In all, posttranslational modifications, whether they involve covalent attachment or deletion, or proteolytic processing, serve to modify the function of nascent proteins. Protein function may be regulated through the activation/inhibition of enzymatic or signaling activities, via the structural stabilization against mechanical stress or protease degradation or by altering trafficking/targeting. In this review, we focus on the proteolytic cleavage of three disparate families of cell-surface receptors. Notch receptors, protease-activated receptors (PARs), and G-protein receptor proteolytic site (GPS) containing receptors all exemplify how posttranslational modification by proteolysis can greatly affect protein function.

2. The proteolytic cleavage of Notch

The Notch receptor is crucial in the development of virtually all metazoans, regulating the temporal and spatial cell-fate decisions of multipotent precursor cells. Notch

is a multiple-domain, single-span membrane protein that exemplifies how posttranslational proteolytic cleavage can play a central role in the maturation, activation, and regulation of protein function. Notch is processed at five distinct stages (Figure 1). The first proteolytic processing of the precursor protein occurs in the endoplasmic recticum (ER) by a signal peptidase, which removes the signal peptide from the N-terminus. The second occurs in the Golgi by a furin-like convertase (Logeat *et al*., 1998) (a Ca^{2+}-dependent serine endoprotease, belonging to the subtilisin/kexin-like family), which cleaves at an RXR/KR dibasic recognition site about 70 amino acids N-terminal to the membrane region. Noncovalent reassociation after processing, results in the expression of a heterodimer at the cell surface, which is essential for the subsequent signaling via CSL (CBF1, Suppressor of Hairless, Lag-1) family of transcription factors (Jarriault *et al*., 1998). Recently, in human Notch, low levels of unprocessed cell-surface molecules have been shown to signal by a CSL-independent mechanism, demonstrating that proteolytic cleavage can have a profound effect by directing the signaling pathway chosen by a cell-surface receptor (Bush *et al*., 2001). The third proteolytic event of Notch occurs upon binding to its ligands, Delta, Serrate, and Jagged. Evidence suggests that the endocytosis of the ligand–receptor complex by the ligand-bearing cell results in a conformational change in the Notch protein. This leads to removal of the ectodomain close to the membrane via an ADAM/TACE protease (a disintegrin and metalloprotease/TNF-α converting enzyme), thus preventing further interactions with ligand-bearing cells (Brou *et al*., 2000). Once the ectodomain has been cleaved, the mechanism of Notch signal transduction differs from that of other proteins relying on phosphorylation or secondary messenger generation in that intramembrane cleavage of Notch is performed by a proteolytic complex termed γ-secretase (Kimberly and Wolfe, 2003). The complex comprises Presenilin, an eight span–membrane protein thought to be an aspartyl protease, Nicastrin a single-span membrane, and other putative proteins. The aspartyl protease activity of Presenilin releases the intracellular domain of Notch, which is then translocated into the nucleus where it interacts with CSL proteins. This either displaces repressing histone deacetylases or recruits transcriptional activators, leading to the activation or suppression of target genes. Finally, Notch signaling is downregulated when the intracellular domain is phosphorylated by a Sel-10 containing complex, resulting in subsequent ubiquitination and targeting for degradation by the proteasome (Hubbard *et al*., 1997; Oberg *et al*., 2001). Similar mechanisms involving regulated intramembrane proteolysis have now been proposed for a number of other receptors including the amyloid precursor protein, the adhesion molecules CD44 and E-Cadherin, a tyrosine kinase receptor ErbB4, LRP, a member of the LDL receptor family, and neurotrophin (Okamoto *et al*., 2001; Kanning *et al*., 2003; May *et al*., 2002; Ni *et al*., 2001; Roncarati *et al*., 2002). These data show that intramembrane cleavage is not unique to Notch but instead is a more widespread signaling phenomenon.

3. Protease-activated receptors

The protease-activated receptors (PAR1–4) are G-protein coupled receptors (GPCRs) that have been implicated in a range of physiological roles including

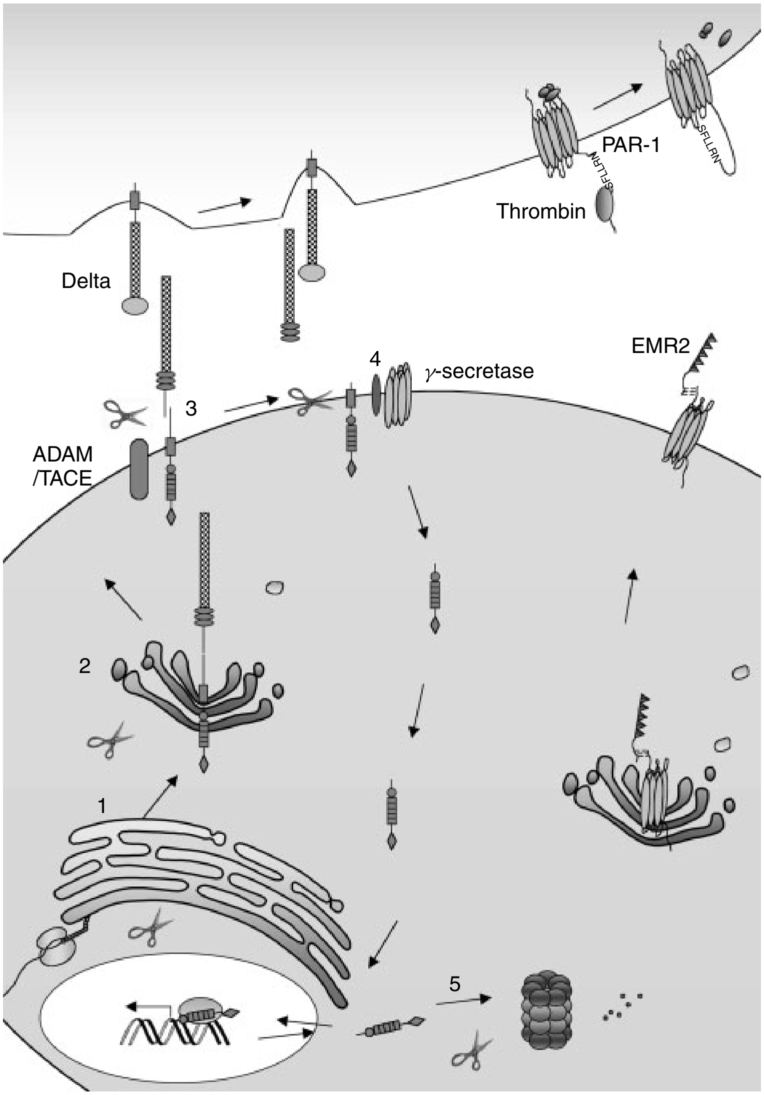

Figure 1 Notch, PAR, and GPS-protein processing. Notch-1: 1. Within the ER, the first of five proteolytic events occurs when the signal peptide is removed by a signal peptidase. 2. Further processing is mediated by a furin-like convertase in the golgi. After cleavage Notch reassociates and is expressed on the cell surface as a heterodimer. 3. The interaction of Delta or other ligands with Notch initiates endocytosis, which in turn induces conformational changes in Notch allowing shedding by an ADAM/TACE protease. 4. A γ-secretase protease complex then cleaves Notch within its membrane domain releasing its intracellular domain that is translocated into the nucleus where it interacts with CSL proteins. 5. Finally, Notch signaling is downregulated when the intracellular domain is phosphorylated by a Sel-10 containing complex, resulting in subsequent ubiquitination and targeting for degradation by the proteasome. PAR-1: After translocation and processing of its signal peptide in the ER, PAR-1 is expressed as a multispan receptor on the cell surface. Cleavage by the serine protease, Thrombin, reveals a previously masked tethered ligand that subsequently interacts with the second extracellular loop, activating the PAR receptor. GPS receptors: EMR2 a leukocyte-restricted receptor is shown as a paradigm for GPS receptors. The protein is initially targeted to the ER where its signal peptide is removed and an autocatalytic processing event occurs. The receptor then reassociates and is transported to the cell surface where it interacts with its ligands as a functional heterodimer. Scissors denote stages at which proteolytic cleavage occurs

platelet activation, inflammation, immune cell function, and embryonic development. However, unlike normal GPCRs, which bind their ligands in a reversible fashion, the PAR receptors are irreversibly activated by specific proteases. After the proteolytic cleavage of the N-terminus, a previously masked peptide sequence acts as a tethered ligand for the receptor causing subsequent signaling.

The mechanism of PAR activation, which was initially demonstrated for PAR-1 while studying platelet activation, now appears to represent a general paradigm for the other family members (Figure 1) (Vu *et al*., 1991). During the search for the human thrombin receptor, it was found that thrombin, a serine protease binds to the ectodomain of PAR-1 and cleaves the N-terminus between Arg41 and Ser42. This causes the unmasking of the peptide sequence SFLLRN that was previously sterically hindered by the proceeding N-terminal residues, thereby allowing it to act as a ligand for PAR-1. Synthetic peptides corresponding to the new N-terminus also act as agonists but are independent of thrombin cleavage. These peptides have proved invaluable in dissecting the crucial residues involved in receptor ligation and have demonstrated that protonation of the new N-terminal serine and the presence of phenylalanine, arginine, and asparagine residues are essential for the interaction with a conserved region within the second extracellular loop of the receptor (Scarborough *et al*., 1992). The binding of synthetic agonists or the N-terminus of postcleaved PAR-1 is thought to cause a conformational change allowing the receptor to interact with heterotrimeric G-proteins. The resulting activation of phospholipase Cβ and production of IP_3 and DAG in turn leads to increases in cytosolic Ca^{2+} levels. This is followed by integrin activation, shape change, release of dense and α-granules, and platelet–platelet aggregation, all of which are associated with platelet activation and the formation of thrombi.

As receptor cleavage effectively results in permanent ligand engagement and receptor activation, it follows that the extent of the cellular response is determined by the termination of PAR signaling. Although the exact mechanisms of desensitization and downregulation of PARs are not well characterized, it is presumed they are similar to other GPCRs. Phosphorylation by GPCR kinases and subsequent interactions with β-arrestins, which have been shown to play an important role in the desensitization of many GPCRs have also been shown to desensitize PAR-1. Receptor internalization and degradation via clathrin-coated vesicles, AP_2 interactions and lysosomal sorting also appear to be crucial in the downregulation of PAR-1 activity.

Although the general mechanism of PAR-1 activation is similar to that of PAR-2, -3, and -4, significant differences have been demonstrated. For example, PAR-2 is the only member of this family that is not cleaved by thrombin. Instead, it is cleaved by a number of trypsin-like serine proteases such as trypsin, neutrophil proteinase 3, factor VIIa/Xa, mast-cell tryptase and membrane-tethered serine protease-1 (Cottrell *et al*., 2003). In addition, PAR-3 is not activated by soluble synthetic peptides. These observations suggest that cleavage-mediated signaling in vivo is likely to be much more complex than initially envisaged, involving many different proteases and signaling mechanisms.

4. GPS-containing receptors

In recent years, a novel proteolytic motif known as the GPCR proteolytic site (GPS) has been identified in over 40 human cell-surface receptors (SMART, **http://smart.embl-heidelberg.de**). The majority of the GPS-containing receptors show homology to class B GPCRs within their transmembrane moieties. However, they also possess large N-terminal extracellular domains containing multiple adhesion motifs, coupled to a GPS-containing region (Fredriksson *et al*., 2003). This has led to the notion that these receptors might couple extracellular adhesion to intracellular G-protein signaling. The receptors, classified as LNB-TM7 receptors include the largest known cell-surface receptor VLG-1 (an impressive 6307 amino acids) (McMillan *et al*., 2002), the receptor for the black widow spider toxin, latrophilin (Lelianova *et al*., 1997), and the leukocyte restricted EGF-TM7 receptors (Stacey *et al*., 2000). Many of these LNB-TM7 receptors have now been demonstrated to undergo early proteolytic processing during protein maturation (Figure 1). Evidence now suggests that the cleavage occurs in the ER and requires an intact GPS region of ∼200 amino acids. The exact structure of this GPS region has not yet been elucidated; however, four conserved cysteines and invariant glycine and tryptophan residues appear to be crucial for cleavage to occur at a conserved membrane proximal site (HX↓S/T). Curiously, the extracellular subunit generated by cleavage tightly reassociates to as few as eight amino acids of the membrane subunit in a noncovalent fashion. It is then expressed on the cell surface as a heterodimer. The fact that the GPS domain is conserved in both vertebrates and invertebrates suggests that this proteolytic event must have an important functional role in receptor activity and is likely to be mediated by a common mechanism. Much work has been performed in the search for the protease(s) that cleave the GPS site but with no success. However, recent work by Lin *et al*. (2004) using purified protein of a GPS receptor, in a cell-free system, has clearly established that the cleavage mechanism is in fact an autocatalytic process occurring via an intramolecular cleavage event. As the GPS motif is highly conserved, it is likely that the autocatalytic event will be a paradigm for the other receptors. So what is the functional significance of the autocatalytic proteolysis? A clue to the potential function has come from studies of the multiple membrane-spanning protein responsible for autosomal-dominant polycystic kidney disease, PKD-1/polycystin-1. Polycystin-1 has been found to mediate Ca^{2+} influx by its interaction with the membrane protein polycystin-2. However, although Polycystin-1 GPS-mutants found in PKD patients have been shown to express normal levels of surface receptor, they do not undergo receptor cleavage or respond in functional assays (Qian *et al*., 2002), indicating that cleavage is essential for receptor signaling. As yet, the functional role of most of the other GPS-containing proteins is not known. However, it is likely that posttranslational cleavage events will play a crucial role in their biological activities.

Although Notch, PAR, and GPS receptor families only represent a small subset of eukaryotic genes, they demonstrate how proteolysis can have profound effects on

the function of proteins. With the renewed focus on proteins in the postgenomic era, there is no doubt that many more protein-cleavage events will soon be discovered, revealing many more intriguing biological mechanisms.

1. Introduction

The redox status of cysteine residues in proteins is essential to maintain the structure and function of numerous enzymes, receptors, and transcriptional factors. It has long been believed that the free sulfhydryl group (−SH) of a cysteine residue reacts easily with reactive oxygen/nitrogen species, resulting in irreversible oxidation, therefore serving as a marker of oxidative stress inside cells. However, recent evidence suggests that reversible posttranslational modifications of reactive cysteines, such as S-nitrosylation and thiolation, play a greater role in cell signaling. S-nitrosylation, in particular, regulates a multitude of physiological processes.

2. S-nitrosylation

Three terms, nitrosation, nitrosylation, and nitration, are frequently used to describe NO-mediated protein modifications. The first two sometimes employed interchangeably. Nitrosation designates the addition of a nitroso group (NO diatomic group), while nitrosylation refers to the addition of a nitrosyl group (NO radical). Thus, covalent attachment of a nitroso group (NO diatomic group) to another chemical group is called nitrosation and the direct incorporation of a nitrosyl group (NO radical) to a metal by a coordinating bond is called nitrosylation. S-nitrosylation, equivalent to S-nitrosation in some literatures, specifically refers to the formation of an S−NO bond between the NO moiety and a sulfur atom in a protein cysteine residue. Nitration is an irreversible modification of the covalent attachment of triatomic group ($-NO_2$) to proteins by peroxynitrite.

S-nitrosylation is a naturally occurring physiological modification that mediates nitric oxide (NO) signaling. Endogenous *S*-nitrosothiols (SNO) can be detected in many organs under physiological conditions (Bryan *et al*., 2004; Jaffrey *et al*., 2001). The production of SNO is directly linked to endogenous nitric oxide synthase (NOS) activities. S-nitrosylation modulates biological activities of cellular key regulators via altering enzymatic activities, and protein−protein or protein−DNA interactions (Gu *et al*., 2002; Matsushita *et al*., 2003; Kim *et al*., 2002). Aberrant S-nitrosylation is associated with selected disease states (Foster *et al*., 2003). In contrast to reversible modifications driven by enzymes, such

as protein phosphorylation, S-nitrosylation may involve fewer constrains, as it involves a simple chemical reaction between thiol groups and a free diffusible radical NO or its derivatives. Several reaction processes have been proposed in the biosynthesis of endogenous SNO (Table 1) (Foster *et al*., 2003).

Signal transduction pathways typically possess temporal and spatial specificity. Evidence for such specificity in S-nitrosylation, although still fragmentary, is beginning to accumulate. For instance, of more than 50 cysteines in ryanodine receptor, only one is nitrosylated. Jaffrey *et al*. (2001) identified a subset of proteins in brain that is S-nitrosylated. There may be several possible scenarios for such specificity. First, free cysteines in the lipophilic pocket of proteins and in the lipid membrane are uniquely susceptible to nitrosylation. NO appears to react with O_2 to form more reactive NO-derived species including NO_2 and N_2O_3 that S-nitrosylate cysteine thiols in target proteins. NO and O_2 prefer hydrophobic environments, in which the rate of formation of NO-derived species is about 300 times faster than in a liquid phase. Second, NO selectively nitrosylates cysteines within an acid–base motif. These charged amino acids in the consensus motif stabilize the reactive thiolated anion, facilitating nucleophilic attack. Third, subcellular localization and calcium-dependent activation of NOS contribute to the selectivity of S-nitrosylation. NO is a free diffusible gas that cannot be stored so that specificity of NO signaling is largely determined by the intracellular compartmentalization of NOS (Bredt, 2003). Thus, the NMDA receptor NR2a and a brain-enriched small G-protein Dexras1, recruited to the postsynaptic protein complex with nNOS by postsynaptic density protein 95 (PSD95) and CAPON respectively, are S-nitrosylated as they are brought into proximity with NO sources (Lane *et al*., 2001; Jaffrey *et al*., 1998; Fang *et al*., 2000).

S-nitrosylation is dynamically regulated in vivo. Steady state levels of S-nitrosylation are determined by the rates of nitrosylation and denitrosylation. S-nitrosylation requires NOS activity, mediated either by eNOS/nNOS activated by Ca^{2+}, or by iNOS induced by cytokines. S-nitrosylation is diminished when NOS activities are depleted genetically or chemically (Bryan *et al*., 2004; Jaffrey *et al*., 2001), suggesting that boosted NO production is required for S-nitrosylation under physiological conditions. Denitrosylation is a process that removes NO from protein thiols. Acute inhibition of NOS activity leads to rapid turnover of *S*-nitrosyl groups,

Table 1 Mechanisms of S-nitrosylation

Cofactors	Chemical reactions	Examples
O_2	$2NO + O_2 \rightarrow 2NO_2$	Ryanodine receptor
Lipid membrane or protein	$NO_2 + NO \rightarrow N_2O_3 \rightarrow {}^{+}NO \ldots NO_2^-$	
Hydrophobic pockets	${}^{+}NO\ NO_2^- + RSH \rightarrow RSNO + NO_2$	
Motif (K/R/H/D/E-C-D/E)	$RSH + NO \rightarrow RSNO$	Ras
Metals (iron, copper)	$NO + M^{n+} \rightarrow M{-}NO$	Hemoglobin β-chain
	$M{-}NO + RSH \rightarrow RSNO + H^+ + M^{n-1}$	
RSNO	$RSNO + R'SH \rightarrow RSH + R'SNO$	Anion exchange protein 1
Superoxide when $[NO] >> [O_2^-]$	$NO + O_2^- \rightarrow ONOO^- \rightarrow 2ONO{-}NO$	*S*-nitrosothiols

RSNO: Protein *S*-nitrosothiols; M: Transient metals.

suggesting that denitrosylation is constitutively active (Bryan *et al*., 2004). Multiple pathways have been found to modulate denitrosylation. Protein S-nitrosylation can be reversed by transnitrosation, a process by which an NO equivalent is transferred from one thiol to other thiols (Foster *et al*., 2003). It can also be decomposed by endogenous reductants such as ascorbate, or by metals such as copper (Foster *et al*., 2003). But the view of denitrosylation as a simple chemical reaction is probably incomplete. Recent studies have found that several enzymes regulate the catabolism of protein SNO. The *S*-nitrosoglutathione reductase (GSNOR), previously named as glutathione-dependent formaldehyde dehydrogenase (GDFDH) or alcohol dehydrogenase III (ADH III), selectively degrades *S*-nitrosoglutathione (GSNO) (Liu *et al*., 2004). Deficiency of GSNOR leads to accumulation of S-nitrosylated proteins and GSNO, suggesting that GSNO, an endogenous NO carrier, mediates the turnover of protein SNO driven by GSNOR (Figure 1). Additionally, cellular SNO is also maintained by the thioredoxin/thioredoxin reductase system (Haendeler *et al*., 2002). Interestingly, Cu/Zn SOD, a superoxide dismutase that catabolizes O^{2-}, also releases NO from GSNO (Johnson *et al*., 2001). As GSNO participates in the metabolism of protein SNO, it should come as no surprise that ceruloplasmin and γ-glutamyl transpeptidase (γ-GT) (Foster *et al*., 2003) that are known to regulate the production and breakdown of GSNO might also regulate the metabolism of protein SNO.

Selective catabolism of protein SNO is of biologically importance either to sustain or switch off NO signaling. Compartmentalization of protein SNO and cellular reductive powers might contribute to this selectivity. S–NO bonds are labile in reductive environment. Therefore, protein SNO in subcellular organelles, including vesicles and mitochondria, in which protein SNO could be shielded from

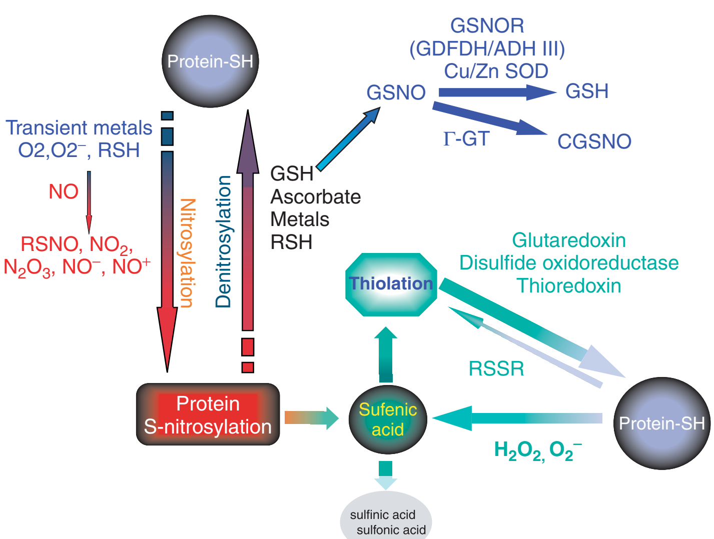

Figure 1 A schematic diagram illustrating the protein thiol modifications mediated by direct chemical or enzyme-assisted reactions in cells

such cellular reductive agents as ascorbate and free reductive thiols in cytosol (1 mM glutathione or GSH), seem to be relatively resistant to denitrosylation. This is exemplified by the fact that translocation of the S-nitrosylated caspase 3 from mitochondria to the reductive cytosol results in its denitrosylation and activation during apoptosis (Mannick *et al*., 2001).

It has been over a decade since NO was discovered as an endogenous signaling molecule generated by NOS. NO signaling was first thought to derive solely from activation of soluble guanylyl cyclase (sGC) and involves binding of NO to the heme moiety in sGC to produce cGMP that can be readily detected. Studies on S-nitrosylation have been limited because of the lack of a more reliable and sensitive detection method. Nevertheless, numerous methods have been developed to detect the S–NO bond. Gas-phase chemiluminescence methods, by using various strategies to cleave the S–NO bond (including photolytic cleavage, Cu^{+}/cysteine and I_2/I^{-}), are used to detect total SNO and individual S-nitrosylated proteins in combination with immunoprecipitation (Bryan *et al*., 2004; Liu *et al*., 2004). Other methods, such as [^{15}N] NMR and mass addition with electrospray ionization, are also used. Unfortunately, these techniques require specialized equipment that is not commonly available (Lane *et al*., 2001). A polyclonal antibody against SNO detects protein S-nitrosylation by immunohistochemistry, western blot, and immunoprecipitation (Matsushita *et al*., 2003). Conventional colorimetric methods including the Saville assay and measurement of the absorbance at 340 nm are not sensitive enough to detect SNO in vivo. Recently, a biotin-switch technique has been developed to identify S-nitrosylated proteins in vivo (Jaffrey *et al*., 2001). This approach provides a convenient tool in general laboratory settings and permits identification in vivo of S-nitrosylated proteins proteomically when coupled to mass spectrometry. The S-nitrosylated peptides can be identified by a modification of this procedure, providing nitrosopeptide mapping analogous to phosphopeptide mapping (Jaffrey *et al*., 2002).

3. Thiolation

Thiolation is another cysteine-based, oxidative, but reversible, posttranslational modification involving formation of mixed disulfides between protein thiols and low molecular weight (LMW) thiols such as GSH. This modification may serve as an antioxidant activity, preventing proteins from oxidative damage such as formation of disulfides among proteins resulting in protein aggregation, and irreversible oxidation of the thiol groups to a higher oxidation state (Thomas *et al*., 1995). Thiolation may be a physiologic cellular response to oxidative stress, mediating redox signaling by reversibly altering activities of cellular proteins (Murata *et al*., 2003). Thiolation is a nonenzymatic chemical reaction between reduced LMW thiols and reactive thiyl radicals or sulfenic acid intermediates that are derived from partial oxidation of protein thiols by a number of cellular oxidants, such as nitric oxide and its derivatives, superoxide anion, reactive lipids, and hydrogen peroxide (Table 2). It also can occur through thiol-disulfide exchange between protein thiols and oxidized glutathione and cysteine (GSSG and cystrine). Thiolation is selective with only some of cysteines in proteins being thiolated (Mallis *et al*., 2001).

Table 2 Mechanisms of thiolation

Mechanisms	Chemical reactions
Thiol-disulfide exchange	Protein-SH + RSSR → protein-S-SR + RS^-
Mediated by thiyl radical or sulfenic acid	Protein SH + ROS/RNS → protein-S*
	Protein-S* + RSH → protein-S-S-R
	Protein SH + ROS/RNS → protein-SOH
	Protein-SOH + RSH → protein-S-S-R
Irreversible oxidation	Protein SH + ROS/RNS → protein-SOH → protein-SO_2H/SO_3H

ROS: Reactive oxygen species; RNS: Reactive nitrogen species; Protein-S*: Protein thiyl radical; RSH: Low molecular weight thiols.

Moreover, it is also protein specific. For example, among GAPDH isozymes, only Tdh3, but not Tdh2, is thiolated when yeast is exposed to H_2O_2, though both isoforms can be thiolated by H_2O_2 in vitro (Grant *et al*., 1999). Thiolation does not apparently correlate well with cellular redox state (Shenton *et al*., 2002). Mechanisms underlying selective thiolation remain unclear. It is generally thought that the targeted cysteines must be exposed to solvent (liquid phase), providing access to LMW thiols in the cytosol. Features of the local microenvironment, such as a high pK_a that enhances ionization of the sulfhydryl groups, promote thiolation. GSH and GSSG are bulky and negatively charged molecules so that electrostatic interaction and steric interference are determinants of thiolation.

Protein thiolation is readily reversible when the oxidative stress is alleviated. Dethiolation is more likely to be an enzymatic process because the rate of direct dethiolation by GSH appears very slow. Indeed, several dithiol family enzymes, including thioredoxin, glutaredoxin, and protein disulfide isomerase, markedly facilitate dethiolation (Thomas *et al*., 1995) (Figure 1). Glutaredoxin specifically turns over thiolation but not other disulfide bonds. Recently, a novel monothiol-glutaredoxin, glutaredoxin 5, has been found to selectively dethiolate Tdh3 isoenzyme of GAPDH in yeast (Shenton *et al*., 2002). Substrate-specific dethiolation has recently been implicated in cell apoptotic signaling (Murata *et al*., 2003).

It is much more straightforward to detect thiolation than S-nitrosylation due to the relatively stable mixed disulfide bonds. In addition, thiolation can be labeled with [^{35}S].

4. Interaction between S-nitrosylation and thiolation

Ionized protein thiols are susceptible both to S-nitrosylation and thiolation. Indeed, many proteins can be nitrosylated or thiolated on the same reactive cysteine, for example, Cys^{181} in H-ras (Mallis *et al*., 2001) and Cys^{199} in oxyR (Kim *et al*., 2002). The S–NO bond is labile and easily oxidized to sulfenic acid that readily reacts with GSH, forming mixed disulfides (Figure 1); thus, protein S-nitrosylation promotes thiolation. Thiolation in vitro requires a higher concentration of GSNO

than does S-nitrosylation (Kim *et al*., 2002). The difference in effectiveness of these two modifications is likely to be determined by the distinctive nucleophilic attack properties of thiolated anions with either the nitrogen or with the sulfur. Electrostatic or steric interference for the bulky and charged GSH restrict access to reactive protein thiols more than small diffusible NO-derived species. Accordingly, S-nitrosylation should have a lower threshold than thiolation in response to NO signaling. Thus, protein S-nitrosylation occurs under normal physiological conditions, while thiolation is most likely to prevail with prolonged nitrosative stress.

Short Specialist Review

Glycosylation in bacteria: that, what, how, why, now what?

Ben J. Appelmelk, Christina M. J. E. Vandenbroucke-Grauls and Wilbert Bitter
Vrije Universiteit Medical Center, Amsterdam, The Netherlands

1. That

The difference between pro- and eukaryotes suddenly appeared smaller when in 1974 Mescher and Strominger demonstrated that prokaryotes *also* could glycosylate their polypeptides. Initial work was on *Archeae* (like *Halobacterium halobium*) but later studies demonstrated that less exotic *Eubacteria* behaved similarly, and the S-layer glycoproteins were for years paradigmatic. More recently, it has become clear that also many common pathogens such as *Campylobacter jejuni*, *Neisseria meningitidis*, *Mycobacterium tuberculosis*, and *Pseudomonas aeruginosa* glycosylate polypeptides, often modifying outer membrane proteins (OMPs) or well-recognized virulence factors such as pili or flagella (Messner and Schaffner, 2003; Power and Reeves, 2003; Schmidt *et al.*, 2003; Szymanski *et al.*, 2003). Thus, the ability to express glycoproteins is widely distributed over the prokaryote kingdom.

2. What

As in eukaryotes, prokaryote glycans can occur O-linked to serine/threonine/tyrosine or N-linked through asparagine (*see* Article 64, **Structure/function of *N*-glycans**, Volume 6, Article 65, **Structure/function of *O*-glycans**, Volume 6, and Article 76, **Analysis of N- and O-linked glycans of glycoproteins**, Volume 6). The eukaryotic consensus motif for N-glycosylation (Ser/Thr-X-Asn) has also been found in prokaryotes. While in eukaryotes, the (N-linked) glycan chains can be grouped into complexes, high mannose and hybrid, diversity in prokaryotes precludes such grouping. Their glycan substitutions vary between simple monosaccharides (Man, GlcNAc, GalNac) and complex oligosaccharides ($n > 15$) that include residues not encountered in man (like pseudaminic acid, an analog of sialic acid); these glycans may even consist of repeating units. Finally, to come full circle, high mannose glycans (8/9 mannoses), similar to those found in eukaryotes are expressed by the intracellular parasite *Chlamydia trachomatis*. Thus, prokaryotes protein glycans show a bewildering diversity and are sometimes completely eukaryotic-like.

3. How

The machinery required for glycosylating bacterial proteins has been elucidated recently in various species, and is best exemplified by *C. jejuni,* in which separate pathways for O- and N-glycosylation have been identified (Szymanski *et al*., 2003). These pathways are also physically separated on the chromosome, each organized in a glycosylation island. The O-glycosylation island (locus) consists of about 50 genes (between Cj1293 and Cj1337 in the genome strain 11168) and is adjacent to the flagellin structural genes *flaA* and *flaB*. Surprisingly, for this size of locus, the glycan chains of flagellin consist of a monosaccharide only (pseudaminic acid and derivatives). However, the degree of glycosylation is unsurpassed for a bacterial protein: 19 Ser/Thr residues carry this monosaccharide (=10% of the MW of native flagellin). For several genes in this locus, a likely role in the biosynthesis of pseudaminic acid could be assigned. For instance, Cj1293 codes for a functional UDP-GlcNAc dehydratase, Cj1313 and Cj1321 are acetyltransferases, and Cj1331 (called *ptmB*) is a CMP-NANA synthetase homolog, hence is likely to be involved in synthesis of the pseudaminic acid-CMP, the hypothesized glycosyl donor of this residue. Strikingly however, the glycosyltransferase itself has not been identified yet.

The N-glycosylation locus (also called *pgl*, for protein glycosylation) is much smaller (Cj1119c-1130c) but puts on a much more complex chain, namely, the heptasaccharide GalNAc-α1,4-GalNAc-α1,4-[Glcβ1,3]GalNAc-α1,4-GalNAc-α1,4-GalNAc-α1,3-bacillosamine (bacillosamine=2,4-diacetamido-2,4,6-trideoxyglucose). This machinery is also called the *general glycosylation pathway*, as it modifies >30 polypeptides that were identified after affinity chromatography with the GalNAc-specific lectin soybean agglutinin and SDS-PAGE. Mechanistic insight on how these glycans are synthesized was obtained though the identification of the Cj1126c (also called *pglB*) as an oligosaccharidyltransferase, highly homologous to its eukaryotic (yeast) counterpart STT3. STT3 transfers completed lipid-bound oligosaccharides to the Asn, as present in the consensus motif Asn-X-Ser/Thr. On the basis of analogy with eukaryotic *N*-glycan synthesis, the following scenario for *C. jejuni N*-glycan synthesis seems plausible (Figure 1): *pglC* (Cj1124c) first attaches an acetylhexosamine (starting with a UDP-acetylhexosamine donor) to a membrane-inserted polyprenyl lipid carrier; the subsequent actions of the *pglF* and other gene products of this locus, which contains at least five glycosyltransferases, form the complete heptasaccharide. Then, in analogy with eukaryotes, the lipid-bound heptasaccharide flip-flops from cytoplasmic to the periplasmic side of the membrane (by Cj1130c, WlaB, an ABC-transporter). The final step takes place when PglB transfers the heptasaccharide to Asn.

While in *C. jejuni* separate pathways exist for protein- and lipid glycosylation, in *P. aeruginosa* these routes intersect and the same trisaccharide is present on pilin and in LPS. Transfer of the trisaccharide from a lipid carrier toward pilin by a rather nonspecific oligosaccharidyltransferase (*pilO*) seems likely; hence, this route has similarities to the N-glycosylation system of *C. jejuni*.

Thus, the prokaryotic glycosylation machinery has been elucidated in quite substantial detail, in particular through whole-genome sequencing but not always functional data (enzyme activities) are available. Clearly, the N-glycosylation

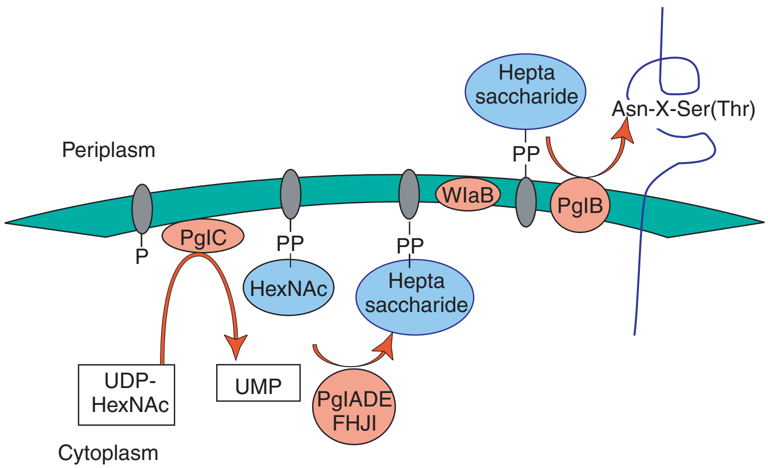

Figure 1 Model for the biosynthesis of N-linked glycoproteins in *Campylobacter jejuni* (adapted from Szymanski CM, Logan SM, Linton D and Wren B (2003) *Campylobacter jejuni* – a tale of two glycosylation systems. *Trends in Microbiology*, **11**, 233–238). Nucleotide-activated sugars are assembled on a lipid carrier, which results in the formation of a specific heptasaccharide. Subsequently, the glycan moiety is flipped across the inner membrane by WlaB (Cj1130c) and transferred to the appropriate asparagine residue by PglB. P: lipid-carrier phosphate; PP: lipid-carrier pyrophosphate; UDP: uridine diphosphate; UMP: uridine monophosphate; HexNAc: acetylhexosamine

pathway, formerly thought to be present in eukaryotes only, is present in Prokaryotes.

4. Why

Recent data suggest that bacterial protein glycosylation has, apart from a stabilizing or structural role, an important role in the adaptation of prokaryotes to their environment, like host–pathogen interaction. Two examples are given below.

4.1. The role of pilin glycosylation in gonococcal pathogenesis

Neisseria gonorrhoeae is the causative agent of gonorrhoea, a disease that can cause major complications upon be dissemination. PilE, the major structural pilin protein, is O-glycosylated with Galα1.3GlcNAc, with *pgtA* coding for the galactosyltransferase (Banerjee *et al*., 2002). In *pgtA*, a poly G-tract can be present, a signature for phase variation through DNA slippage (*see* Article 62, **The neisserial genomes: what they reveal about the diversity and behavior of these species**, Volume 4) (slipped-strand mispairing). When, for instance, a G14 tract is present in the parent bacterial cell, an intact GalT is formed and a disaccharide glycan is present. Upon cell division, owing to DNA slippage, phase-variant daughter cells arise with a G15 tract, which causes downstream frame-shifting and a

concomitant lack of a functional GalT and of galactosylated pili. Strikingly, strains that cause noncomplicated gonorrhea (i.e., confined to genitourinary epithelium) lack G-tracts (pili subunits are always modified), while disseminating strains display phase variation. A plausible mechanism is that the gonococci are recognized by an epithelial lectin and that for invasiveness prior detachment through phase variation is essential. Alternatively, the disaccharide might be the target of bactericidal serum antibodies, and hence phase variation would serve immune evasion.

4.2. *The role of Pseudomonas syringae flagellin glycosylation in host specificity*

Pseudomonas syringae is a plant pathogen of tobacco, soybean, tomato and others. Within *P. syringae*, pathovars (pv.) exist with strict host specificity (Takeuchi *et al*., 2003): while *P. syringae* pv. tabaci can infect its host the tobacco plant (compatibility), it is not compatible with nonhost plants such as soybean; vice versa, *P. syringae* pv. glycinea is compatible with soybean but not with tobacco. When a pathovar encounters a noncompatible host, a host defense (hypersensitivity, HR) reaction occurs, involving host cell apoptosis. Glycosylated pili are responsible for this HR reaction. In *P. syringae* pv. glycinea, a small glycosylation island (three orfs of which two are glycosyltransferases) was detected between two flagellin structural genes *fliC* and *fliL*. Disruption of the glycosyltransferases led to the production of non-/less-glycosylated pili and compatibility with tobacco, that is, this bacterium did no longer elicit the HR (Figure 2) reaction and could cause symptoms in this normally nonhost. Conversely, the mutants did not infect their original soybean host any more. These data prove that specific glycosylation and recognition is responsible for host specificity.

5. Now what?

By necessity, the study of prokaryote glycosylation started as “stamp collection”, that is, collecting structures of sometimes complex prokaryote glycan residues or chains. Now, the field is rapidly moving ahead into understanding the functional significance of glycosylation. The driving force is the explosion of -omics, including genomics, proteomics, and glycomics (Drickamer and Dell, 2002; *see also* Article 74, **Glycoproteomics**, Volume 6 and Article 75, **Mass spectrometry**, Volume 6). Protein spots present in 2D gels can be picked and, owing to the revolution in mass spectrometry (high throughput, enhanced sensitivity), be identified almost momentarily, compared to whole genomes, and assigned a function through increasingly sophisticated bioinformatics. In parallel, the field benefits from developments in carbohydrate synthesis (oligosaccharide libraries and glyco-chips). From the picture that is now emerging, it becomes clear that as in eukaryotes, prokaryote glycans can serve as information carriers, fine-tuning the interplay between prokaryotes and their environment, including human and nonhuman hosts.

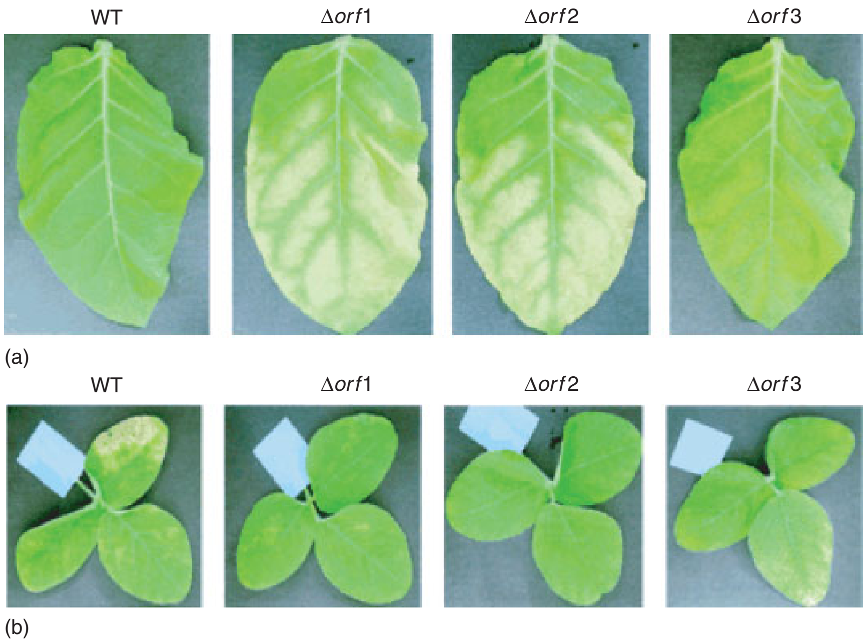

Figure 2 The role of pilin glycosylation on compatibility of *Pseudomonas syringae* pv. glycinea with tobacco (a) and soy (b) (Reproduced from Takeuchi K, Taguchi F, Inagaki Y, Toyoda K, Shraishi T and Ichose Y (2003) Flagellin glycosylation in *Pseudomonas syringae* pv. glycinea and its role in host specificity. *Journal of Bacteriology*, **185**, 6658–6665 by permission of American Society for Microbiology). Wild-type *Pseudomonas syringae* pv. glycinea is not compatible with (i.e., cannot infect) its nonhost tobacco but is so with its host soy, where it causes symptoms (whitish discoloration). After inactivation of glycosyltransferases required for pilin glycosylation (Δ*orf1* or Δ*orf2*), mutants are compatible with tobacco but now compatibility with the original host soy is lost

Short Specialist Review

O-glycan processing

Anthony P. Corfield
University of Bristol, Bristol, UK

1. Introduction

Proteins may carry glycan chains linked by O- (*see* Article 65, **Structure/function of *O*-glycans**, Volume 6) or N-glycosidic bonds (*see* Article 64, **Structure/function of *N*-glycans**, Volume 6) to the protein backbone. The biosynthesis and processing for each of these two types of glycan is quite different, reflecting discrete regulation of structure and biological function. The synthesis and processing of *O*- and *N*-glycans occurs in the endoplasmic reticulum and the Golgi through the controlled action of a series of glycosyltransferase and glycosidase reactions. The *N*-glycan chains are assembled through lipid (dolichol) intermediates and further processed by a series of specific glycosidases (*see* Article 64, **Structure/function of *N*-glycans**, Volume 6). This is not the case for the O-glycans that do not rely on lipid intermediates.

The formation and processing of *N*- and *O*-glycans is regulated at the level of gene expression, mRNA, and enzyme protein activity. Additional control exists through substrate and cofactor concentrations at the subcellular site of synthesis. These processes are integrated to yield the huge variety of glycan structures utilized by different species, tissue types, cell types, and observed in different states of development and differentiation.

This short review focuses on the formation and processing of the Ser (Thr)-GalNAc class of *O*-glycans and those biological processing events for specific proteins that depend on the occurrence and manipulation of their O-linked oligosaccharides. Further examples of *O*-glycan processing events can be found for *N*-acetylglucosamine linked to serine or threonine (*O*-GlcNAc) on cytosolic and nuclear proteins (*see* Article 72, **O-linked *N*-acetylglucosamine (*O*-GlcNAc)**, Volume 6) and fucose and glucose O-linked to serine or threonine in the epidermal growth factor domains in a variety of proteins.

2. Processing of *O*-glycan chains

The assembly of the Ser (Thr)-GalNAc class of *O*-glycans is achieved by the action of a series of biosynthetic pathways that are located in regions of the endoplasmic reticulum and Golgi apparatus (*see* Article 65, **Structure/function of**

***O*-glycans**, Volume 6). These pathways involve largely glycosyltransferases, but also include *O*-glycan specific sulfotransferases and *O*-acetyltransferases, leading to the formation of defined oligosaccharide sequences, which have been confirmed by structural analysis (Brockhausen, 1999). The pathways lead to predictable structures with core, backbone, and peripheral units that are found linked to specific proteins. The subcellular organization of the enzymes, in particular the glycosyltransferases, into functional units acting on individual proteins is believed to deliver the specific glycosylation patterns found for each protein (Brockhausen, 1999). The examination of the biological function of individual proteins and the status of their glycans has revealed that processing of the oligosaccharide chains frequently plays a role (Van den Steen *et al*., 1998). The processing of *O*-glycans to generate biologically active glycoproteins may arise in several ways. Firstly, the attachment of *O*-glycans due to the sequential action of glycosyltransferases by the known pathways may deliver completed structures through the action of all enzymes in the pathways. However, in some cases, "incomplete" or truncated structures are formed, which have biological function. These glycans arise because of the action of a reduced number of glycosyltransferases in the biosynthetic units. The addition of backbone and/or peripheral monosaccharides does not occur and shortened or "incomplete" oligosaccharides result. This is the case for IgA hinge region *O*-glycans (Novak *et al*., 2000). Alternatively, the processing of completed *O*-glycan chains may be made by the action of catabolic enzymes including glycosidases, sulfatases, or esterases. Thus, *O*-glycans can be processed while attached to proteins in a manner analogous to the normal catabolic pathways responsible for the degradation and recycling of glycoproteins. These events usually involve removal of terminal residues such as sialic acids, fucose, or sulfate but can also include the total removal of *O*-glycan chains through the combined action of several exoglycosidases such as sialidases, fucosidase, and galactosidases together with endoglycosidases and *O*-glycanases responsible for the internal cleavage of the oligosaccharide chains or their removal for the peptide backbone respectively. The literature describing such events suggests that a variety of glycoproteins are associated with *O*-glycan processing phenomena and some examples are given below.

3. The role of O-linked glycosylation in protein expression and processing

Many O-glycosylated glycoproteins that are known to be biologically processed rely on their *O*-glycans to achieve these events. This posttranslational modification is an integral step enabling the function of the mature glycoprotein in vivo. Examples have been reported in several contexts and are grouped below to represent a selection from the current literature. Some of these aspects can also be found summarized in Article 65, **Structure/function of *O*-glycans**, Volume 6. In addition, glycoproteins with both *O*- and *N*-glycans are common and differential roles for the glycan chains relating to processing and other biological functions have been reported.

3.1. Protein synthesis and expression

The expression of proteins can be modulated at different stages by the presence of glycan chains. The synthesis of mature glycophorin A has been found to be dependent on the presence of *O*-glycans when expressed in glycosylation-deficient CHO cells. In this case, the *N*-glycans normally present in glycophorin A are not necessary for expression (Remaley *et al*., 1991). Further investigation showed that expression of glycophorin A without *O*-glycans could be achieved provided specific *N*-glycan structures were present. Thus, independent expression of *O*- and *N*-glycans can enable glycophorin A expression.

3.2. Proteolytic processing

A number of proteins depend on the addition of *O*-glycans at specific sites in order to prevent proteolytic cleavage destroying biological activity or preventing stable residence of the protein at its required subcellular location.

Insulin-like growth factor-2 (IGF-2) is expressed in most embryonic tissues and is required for normal development during gestation but is only expressed in adults during tumorigenesis. Two forms occur in serum – a big IGF-2 and a normal form. Proteolytic cleavage occurs to convert big to normal form, and this is mediated at Thr75 by the presence of an *O*-glycan. Big IGF-2 has no *O*-glycan and is not clipped (Duguay *et al*., 1998).

The expression of LDL receptors at the cell surface relies on the presence of *O*-glycan chains, which prevent proteolytic cleavage of the extracellular domains of these proteins (Kozarsky *et al*., 1988). A further example is the transferrin receptor (TfR). TfR is normally transported to the cell surface and then cycles between the cell surface and the endosomes. A soluble form, sTfR, is formed by proteolytic cleavage in the endosomes. The protease responsible is sensitive to the presence of an *O*-glycan at Thr104. Desialylation also abolishes the protection of the *O*-glycans against proteolytic activity. (Rutledge and Enns, 1996).

Human meprinβ, a member of the astacin family of zinc metalloendopeptidases, shows similar properties of proteolytic release from the cell surface. The O-linked carbohydrate side chains are clustered around a 13 amino acid sequence that contains the main cleavage site for proteolytic processing of the subunit. Prevention of O-glycosylation by specific inhibitors leads to enhanced proteolytic processing and the consequence is an increased release of the enzyme (Leuenberger *et al*., 2003).

Further examples of proteolytic processing are found for the blood clotting factors X and Xa.

The activation of the glycoproteins X and Xa occurs through proteolytic cleavage, by factor IXa and its cofactor VIIIa in the intrinsic cascade and by factor VIIIa and tissue factor in the extrinsic cascade, ultimately leading to thrombin formation. The activation of factor X has been reported to depend on the presence of sialic acid in *O*-glycans as asialo forms show reduced activation. This remains controversial, as other reports have not observed this relationship. However, the removal of the

O-glycans from factor X results in a significant reduction in the k_{cat} for the activation reaction (Inoue and Morita, 1993).

An example where O-glycosylation promotes proteolytic action in processing is found for CD44 in cells of melanocytic lineage. The proteolytic cleavage and shedding is dependent on the presence of partial or complete O-glycosylation of four serine-glycine motifs localized in the membrane-proximal CD44 ectodomain. Mutation of these serine residues, as well as extensive metabolic O-deglycosylation, block spontaneous CD44 shedding (Gasbarri *et al*., 2003).

3.3. Subcellular localization of proteins

The transport of proteins to the Golgi apparatus from the endoplasmic reticulum is closely linked with O-glycosylation. The biosynthesis, maturation, and intracellular transport of galactosyltransferase, an established trans-Golgi enzyme, are disrupted by brefeldin A that induces a microtubule-dependent backflow of Golgi components to the endoplasmic reticulum. The targeting of the galactosyltransferase for the Golgi apparatus is dependent on O-glycosylation (Bosshart *et al*., 1991). Brefeldin A has also been used to demonstrate O-glycosylation of Ribophorin I, a type I transmembrane glycoprotein specific to the rough endoplasmic reticulum. Brefeldin A treatment leads to O-glycosylation of Ribophorin I by glycosyltransferases that are redistributed from the Golgi apparatus to the endoplasmic reticulum (Ivessa *et al*., 1992).

Human neurotrophin receptor (p75 NTR) contains a cluster of O-glycans in the ectodomain located close to the membrane. The transport and sorting of p75 NTR in Caco-2 cells requires these O-glycans. After initial synthesis, the receptor is targeted to the basolateral membrane and subsequently migrates to the apical membrane. Localization to the apical surface is controlled jointly by the O-glycans together with a membrane anchor domain (Breuza *et al*., 1999).

3.4. Developmental expression

The expression of *O*-glycans during developmental processes associated with specific biological activity has been reported. Two examples illustrate this phenomenon.

The CD8$\alpha\beta$ coreceptor possesses an O-glycosylated polypeptide stalk connecting the glycoprotein to the thymocyte surface. Immature CD4(+) CD8(+) double-positive thymocytes bind major histocompatibility complex class I (MHCI) tetramers more avidly than mature CD8 single-positive thymocytes. This differential binding is regulated by a developmentally expressed sialyltransferase (ST3Gal-I) leading to O-glycan modification. The appearance of core 1 sialic acid linked to CD8β on mature thymocytes decreases CD8$\alpha\beta$ -MHCI avidity and thus modulates the binding of dimeric CD8 to MHCI (Moody *et al*., 2001).

The brush border proteins pro-sucrase-isomaltase (pro-SI) and dipeptidyl peptidase IV (DPPIV) are sorted for apical location during the differentiation of the crypt cells. These glycoproteins have both *N*- and *O*-glycans. Full O-glycosylation

is mediated by the N-glycans and the subsequent polarized sorting of these proteins to the apical membrane requires intact *O*-glycans. This example demonstrates interrelated but distinct roles for *N*- and *O*-glycans and their processing in brush border enzyme expression during intestinal cell differentiation. (Naim *et al*., 1999).

4. Immune cell expression and response

A regulatory function for T-lymphocyte Core 2 β-1,6-*N*-acetylglucosaminyltransferase, (C2GnT) in the peripheral immune system has been identified.

CD43 is the major cell-surface glycoprotein and an activation antigen expressed on both CD4 and CD8 single-positive T lymphocytes and carries core 2 O-glycan structures. Downregulation of the activation antigen occurs in thymic positive selection implying that the C2GnT modulated expression of CD43 glycoforms is involved in thymic selection events. (Ellies *et al*., 1996).

Additional support for this type of role for the Core 2 β-1,6-*N*-acetylglucosaminyltransferase comes from overexpression of the enzyme in transgenic mice. Isolation of T lymphocytes from these mice showed a reduced immune response due to impaired cell–cell interaction (Tsuboi and Fukuda, 1997).

Short Specialist Review

O-Mannosylation

Tamao Endo
Tokyo Metropolitan Institute of Gerontology, Tokyo, Japan

1. Introduction

Over 60% of the proteins produced by the human body are thought to contain sugar chains (*see* Article 62, **Glycosylation**, Volume 6). Recent data have revealed the importance of sugar chains as biosignals for multicellular organisms, including cell–cell communication, intracellular signaling, protein folding, and targeting of proteins within cells. There is growing evidence that sugar chains have a variety of roles in cellular differentiation and development, as well as in disease processes.

The major sugar chains of glycoproteins can be classified into two groups according to their sugar-peptide linkage regions. Those that are linked to asparagine (Asn) residues of proteins are termed *N*-glycans (*see* Article 64, **Structure/function of *N*-glycans**, Volume 6), while those that are linked to serine (Ser) or threonine (Thr) residues are called *O*-glycans (*see* Article 65, **Structure/function of *O*-glycans**, Volume 6). In *N*-glycans, the reducing terminal *N*-acetylglucosamine (GlcNAc) is linked to the amide group of Asn via an aspartylglycosylamine linkage. In *O*-glycans, the reducing terminal *N*-acetylgalactosamine (GalNAc) is attached to the hydroxyl group of Ser and Thr residues. In addition to the abundant *O*-GalNAc forms, several unique types of protein *O*-glycosylation have been found, such as *O*-linked fucose, glucose, GlcNAc (*see* Article 72, **O-linked *N*-acetylglucosamine (*O*-GlcNAc)**, Volume 6), and mannose, which have been shown to mediate diverse physiological functions. For example, *O*-mannosylation has recently been shown to be important in muscle and brain development.

2. Structure of *O*-mannosyl glycan

O-Mannosylation is known as a yeast-type modification, and *O*-mannosylated glycoproteins are abundant in the yeast cell wall (Strahl-Bolsinger *et al*., 1999). In unicellular eukaryotic organisms, all *O*-mannosyl glycan structures elucidated so far are neutral linear glycans consisting of 1 to 7 mannose residues (Figure 1). *O*-Mannosylation of proteins has been shown to be vital in yeast, and its absence may affect cell wall structure and rigidity. Additionally, a deficiency in protein *O*-mannosylation in the fungal pathogen *Candida albicans* leads to defects in multiple cellular functions, including expression of virulence. In addition to fungi and yeast,

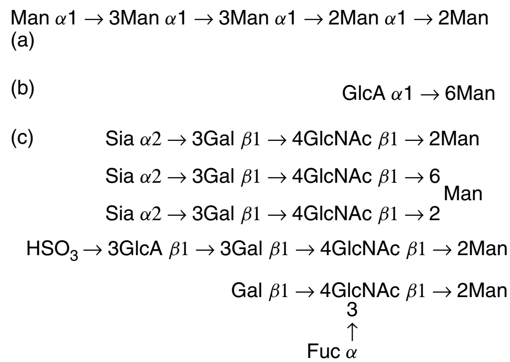

Figure 1 *O*-Mannosyl glycans found in (a) yeast, (b) clam worm, and (c) mammals. Man: mannose; GlcA: glucuronic acid; Sia: sialic acid; Gal: galactose; GlcNAc: *N*-acetylglucosamine; Fuc: fucose

clam worm has an *O*-mannosyl glycan (a glucuronylα1-6mannosyl disaccharide) in skin collagen (Spiro and Bhoyroo, 1980).

Mammalian *O*-mannosylation is an unusual type of protein modification that was first identified in chondroitin sulfate proteoglycans of brain, and is present in a limited number of glycoproteins of brain, nerve, and skeletal muscle (Endo, 1999). In brief, one of the best known *O*-mannosyl-modified glycoproteins is α-dystroglycan, which is a central component of the dystrophin-glycoprotein complex isolated from skeletal muscle membranes. We previously found that the glycans of α-dystroglycan include *O*-mannosyl oligosaccharides and that a sialyl *O*-mannosyl glycan, Siaα2-3Galβ1-4GlcNAcβ1-2Man, is a laminin-binding ligand of α-dystroglycan (Chiba *et al*., 1997). Interestingly, we found the same *O*-mannosyl glycan in rabbit skeletal muscle α-dystroglycan. After our reports of the sialylated *O*-mannosyl glycan, an HNK-1 epitope (sulfoglucuronyl lactosamine) carrying *O*-mannosyl glycan (HSO_3-3GlcAβ1-3Galβ1-4GlcNAcβ1-2Man) was detected in total brain glycopeptides. It is noteworthy that these oligosaccharides have not only 2-substituted mannose but also 2,6-disubstituted mannose. Further, dystroglycan from sheep brain has a Galβ1-4(Fucα1-3)GlcNAcβ1-2Man structure and mouse J1/tenascin, which is involved in neuron-astrocyte adhesion, contains the *O*-mannosyl glycans. Therefore, it is likely that a series of *O*-mannosyl glycans, with heterogeneity of mannose-branching and peripheral structures, is present in mammals. Further studies are needed to clarify the distribution of such *O*-mannosyl glycans in various tissues.

3. Biosynthesis of *O*-mannosyl glycan

Identification and characterization of the enzymes involved in the biosynthesis of mammalian type *O*-mannosyl glycans will help to elucidate the function and regulation of expression of these glycans.

A key difference among yeast, clam worm, and mammalian-type *O*-mannosyl glycans is that those in mammals have the GlcNAc β1-2Man linkage (Figure 1).

This linkage is assumed to be catalyzed by a glycosyltransferase, UDP-GlcNAc: protein *O*-mannose β1,2-*N*-acetylglucosaminyltransferase (POMGnT1). POMGnT1 catalyzes the transfer of GlcNAc from UDP-GlcNAc to *O*-mannosyl glycoproteins, and human *POMGnT1* gene was cloned (Yoshida *et al*., 2001). The nucleotide sequence indicated that human POMGnT1 is a 660 amino acid protein and is a type II membrane protein. This topology was similar to the topologies of other Golgi glycosyltransferases. As described already, mammalian *O*-mannosyl glycan has 2,6-disubstituted mannose. Very recently, a gene for this 6-branching enzyme (GnT-IX) has been cloned (Inamori *et al*., 2004).

In yeast, the family of protein *O*-mannosyltransferases catalyzes the transfer of a mannosyl residue from dolichyl phosphate mannose (Dol-P-Man) to Ser/Thr residues of certain proteins (Strahl-Bolsinger *et al*., 1999). However, attempts to detect protein *O*-mannosyltransferase activity and to characterize the enzyme(s) responsible for the biosynthesis of *O*-mannosyl glycans in vertebrates have not been successful. Two human homologs, *POMT1* and *POMT2*, were found but their gene products did not show any protein *O*-mannosyltransferase activity (Jurado *et al*., 1999; Willer *et al*., 2002). POMT1 and POMT2 share almost identical hydropathy profiles that predict both to be integral membrane proteins with multiple transmembrane domains. Recently, we developed a new method to detect the enzymatic activity of protein *O*-mannosyltransferase in mammalian cells and tissues. Using this new method, we demonstrated that human POMT1 and POMT2 have protein *O*-mannosyltransferase activity, but only when they are coexpressed (Manya *et al*., 2004). This suggests that POMT1 and POMT2 form a hetero-complex to express enzymatic activity similar to the complex in yeast (Girrbach and Strahl, 2003). *POMT1* and *POMT2* are expressed in all human tissues, but *POMT1* is highly expressed in fetal brain, testis, and skeletal muscle, and *POMT2* is predominantly expressed in testis (Jurado *et al*., 1999; Willer *et al*., 2002). *O*-Mannosylation seems to be uncommon in mammals, and only a few *O*-mannosylated proteins have been identified. It will be of interest to determine the regulatory mechanisms for protein *O*-mannosylation in each tissue.

Enzymes for galactosylation, sialylation, fucosylation, glucuronylation, or sulfation of *O*-mannosyl glycans are not identified yet.

4. Defects of *O*-mannosylation and congenital muscular dystrophies

Muscular dystrophies are genetic diseases that cause progressive muscle weakness and wasting (Burton and Davies, 2002). Recent data suggest that aberrant *O*-mannosylation of α-dystroglycan is the primary cause of some forms of congenital muscular dystrophy and neuronal migration disorder.

Muscle-eye-brain disease (MEB: OMIM 253280) is an autosomal recessive disorder characterized by congenital muscular dystrophy, ocular abnormalities, and brain malformation (type II lissencephaly). MEB has been observed mainly in Finland. After we screened the entire coding region and the exon/intron flanking sequences of the *POMGnT1* gene for mutations in patients with MEB, we identified

13 independent disease-causing mutations in these patients (Taniguchi *et al*., 2003; Yoshida *et al*., 2001). We have not detected these 13 substitutions in any of the 300 normal chromosomes, indicating that they are pathogenic and that the *POMGnT1* gene is responsible for MEB. To confirm that the mutations observed in patients with MEB are responsible for the defects in the synthesis of *O*-mannosyl glycan, we expressed all of the mutant proteins and found that none of them had enzymatic activity (Manya *et al*., 2003; Yoshida *et al*., 2001). Together, these findings indicate that MEB is inherited as a loss-of-function of the *POMGnT1* gene. If POMGnT1 does not work, no peripheral structure can be formed on *O*-mannosyl glycans. Because these structures are involved in adhesive processes, a defect of *O*-mannosyl glycan may severely affect cell migration and cell adhesion. Additionally, a selective deficiency of α-dystroglycan in MEB patients was found. This finding suggests that α-dystroglycan is a potential target of POMGnT1 and that hypoglycosylation of α-dystroglycan may be a pathomechanism of MEB. MEB muscle and brain phenotypes can be explained by abnormal *O*-mannosylation.

Walker–Warburg syndrome (WWS: OMIM 236670) is another form of congenital muscular dystrophy that is characterized by severe brain malformation (type II lissencephaly) and eye involvement. Patients with WWS are severely affected from birth and usually die within their first year. WWS has a worldwide distribution. Recently, 20% of WWS patients (6 of 30 unrelated WWS cases) has been found to have mutations in *POMT1* (Beltrán-Valero de Bernabé *et al*., 2002), but none of the 30 cases studied had mutations in another homolog, *POMT2*. This suggests that other as yet unidentified genes are responsible for this syndrome.

In WWS patients, as in MEB patients, a highly glycosylated α-dystroglycan was selectively deficient in skeletal muscle. WWS and MEB are clinically similar disorders, but WWS is a more severe syndrome than MEB. The difference of severity between the two diseases may be explained as follows. If POMGnT1, which is responsible for the formation of the GlcNAcβ1-2Man linkage of *O*-mannosyl glycans, is nonfunctional, only *O*-mannose residues may be present on α-dystroglycan in MEB. On the other hand, *POMT1* mutations cause complete loss of *O*-mannosyl glycans in WWS. It is possible that the attachment of a single mannose residue on α-dystroglycan in MEB is responsible for the difference in the clinical severity of WWS and MEB.

Interestingly, the *rt* mutation in *Drosophila*, which causes defects of myogenesis, was found to be due to a mutation in a homolog of *POMT1* (Martin-Blanco and Garcia-Bellido, 1996; Willer *et al*., 2002). Although the *rt* gene product is not known to initiate the biosynthesis of *O*-mannosyl glycans, *O*-mannosylation is an evolutionarily conserved protein modification (Endo, 1999), and may be essential for muscle development in both vertebrates and invertebrates.

After reporting that MEB and WWS are caused by defects of *O*-mannosylation, some muscular dystrophies have been suggested to be caused by abnormal glycosylation of α-dystroglycan, for example, Fukuyama-type congenital muscular dystrophy (FCMD: OMIM 253800), congenital muscular dystrophy type 1C (MDC1C: OMIM 606612), congenital muscular dystrophy type 1D (MDC1D), and the myodystrophy (*myd*) mouse. However, although highly glycosylated α-dystroglycan was found to be selectively deficient in the skeletal muscle of these patients and the gene products were thought to be putative glycosyltransferases, it is still unclear

due to the defects of *O*-mannosylation. Identification of these defects may provide new clues to the glycopathomechanism of muscular dystrophy.

5. Conclusions

O-Mannosylation is an uncommon protein modification in mammals, but it is important in muscle and brain development. Since a few *O*-mannosylated proteins have been identified, further proteomic studies are needed to clarify the distribution of *O*-mannosyl glycans in various tissues and to examine their changes during development. Future studies may also reveal that presently uncharacterized forms of muscular dystrophy are caused by defects in other glycosyltransferases. A major challenge will be to integrate the forthcoming structural, cell biological, and genetic information to understand how α-dystroglycan *O*-mannosylation contributes to muscular dystrophy and neuronal migration disorder.

O-linked *N*-acetylglucosamine (*O*-GlcNAc)

Stephen A. Whelan and Gerald W. Hart
The Johns Hopkins University School of Medicine, Baltimore, MD, USA

1. Introduction

O-linked *β*-*N*-acetylglucosamine (*O*-GlcNAc) was discovered in 1984 in murine lymphocytes (Torres and Hart, 1984). Virtually all of the *O*-GlcNAc modification is located on nucleocytoplasmic proteins (Holt and Hart, 1986), thus disproving the dogma that glycosylated proteins were only secreted or associated with biological membranes such as ER, Golgi, and other subcellular organelles. *O*-GlcNAc was shown to be both abundant and dynamic, occurring exclusively on serine/threonine residues. *O*-GlcNAc, like phosphorylation, has been detected on functionally diverse types of proteins including, kinases and signal transduction molecules, phosphatases, cytoskeletal proteins, tumor suppressors, hormone receptors, nuclear pore proteins, oncogenes, transcription factors, transcriptional and translational machinery, and viral proteins (Hart, 1997; Whelan and Hart, 2003).

O-GlcNAc plays an analogous role to phosphorylation in cellular regulation with rapid cycling in response to cellular signaling. *O*-GlcNAc occurs at sites that are also modified by protein kinases. *O*-GlcNAc is often reciprocal with phosphorylation at or near adjacent sites on proteins such as, c-Myc, estrogen receptor-*β*, and RNA Pol II (for review, see Hart, 1997). Serine and threonine residues may exist in at least three states, glycosylated, phosphorylated, or unmodified. Multiple *O*-GlcNAc and phosphorylation sites dramatically increase the complexity of protein regulation. The cell's proteome is further complicated with combinations of other abundant posttranslational modifications, as well as acetylation, methylation, and ubiquination. The functions of *O*-GlcNAc modification remain elusive due to the technical difficulties associated with the study of this saccharide. Recently, a number of tools and proteomic techniques have allowed initial deciphering of the complexity of the role of *O*-GlcNAc in the proteome (Roquemore *et al*., 1994; Whelan and Hart, 2003).

2. Enzymatic addition of *O*-GlcNAc

O-linked *β*-*N*-acetylglucosamine transferase (OGT) is the enzyme responsible for the addition of *O*-GlcNAc to nucleocytoplasmic proteins (Haltiwanger *et al*., 1990).

However, unlike the many kinases, there is currently only one known eukaryotic gene that encodes the catalytic subunit of OGT. In addition, knockout studies of the *OGT* gene showed that OGT resides on the X chromosome (Xq13.1) and is necessary for embryonic stem cell viability (Shafi *et al*., 2000). OGT is also evolutionarily conserved from *Caenorhabditis elegans* to man, with rat and human sequences being virtually identical (>99%), further indicating the importance of this enzyme's function in metazoans (for review, see Iyer and Hart, 2003).

Although there are multiple splice variants of OGT, the main native enzyme is composed of three identical 110-kDa peptides (Kreppel *et al*., 1997; Lubas *et al*., 1997). There is also a 78-kDa OGT subunit that is expressed in some tissues, which may be a result of proteolysis or derived via an alternate start site from OGT cDNA. A 103-kDa mitochondrial isoform has also been described (Hanover *et al*., 2003). The TPR domain of OGT is involved in protein–protein interactions as well as trimerization and stability, allowing OGT to interact with a large variety of proteins, including the characterized mSin3A (Yang *et al*., 2002) and OIP106/GRIF-1 (for review, see Iyer and Hart, 2003). OGT itself is modified by *O*-GlcNAc and by tyrosine phosphorylation, suggesting it may be regulated by tyrosine kinase–mediated signal transduction cascades (Kreppel *et al*., 1997).

3. Enzymatic removal of *O*-GlcNAc from proteins

Nucleocytoplasmic β-D-*N*-acetylglucosaminidase (*O*-GlcNAcase) hydrolyzes *O*-GlcNAc (Dong and Hart, 1994). *O*-GlcNAcase is also highly conserved throughout evolution from *C. elegans* to man. *O*-GlcNAcase is a member of the GCN5-related acetyltransferases family (GNAT), with the C-terminal half having the *O*-GlcNAcase activity and the N-terminal half containing putatively weak hyaluronidase activity (Schultz and Pils, 2002). *O*-GlcNAcase is ubiquitously expressed in two forms, a 130-kDa form that is primarily found in the cytosolic fraction and a nuclear localized inactive 75-kDa splice variant.

4. *O*-GlcNAc is a nutrient sensor

The hexosamine biosynthetic pathway (HBP) is responsible for the conversion of 2–5% of the glucose that enters the cell into uridine 5′-diphosphate (UDP)-GlcNAc, the activated sugar donor for OGT. OGT is highly responsive to intracellular UDP-GlcNAc concentrations having varying K_m values for the addition of *O*-GlcNAc to proteins (Kreppel and Hart, 1999). Within the cell, *O*-GlcNAc levels correlate with the level of UDP-GlcNAc. OGT and *O*-GlcNAc appear to be nutrient sensors, since UDP-GlcNAc synthesis requires and/or responds to glucose, amino acid, fatty acid, and nucleotide metabolism (for review, see Wells *et al*., 2003).

5. Physiological function

O-GlcNAc dysregulation has been implicated in disease pathologies such as Alzheimer's disease, cancer, and Type II Diabetes (for review, see Whelan and Hart,

2003). The etiology of Alzheimer's disease involves the formation of neurofibrillary tangles due to the hyperphosphorylation of the microtubule associated protein, tau. Under normal conditions, tau is modified by *O*-GlcNAc. It is hypothesized that *O*-GlcNAc modification protects against hyperphosphorylation and the etiology of Alzheimer's disease.

Primary normal breast tissue compared to breast cancer tissue was shown to have decreased *O*-GlcNAc levels and increased *O*-GlcNAcase activity. More specifically, the proto-oncogene c-Myc mutational hot spot (Thr58) for Burkitt's lymphoma is also the major *O*-GlcNAc modification site. Induction of insulin resistance, the hallmark of type II diabetes, by glucose, glucosamine, or by PUGNAc inhibition of *O*-GlcNAcase, results in hyper *O*-GlcNAc modification of many proteins, including downstream insulin signaling proteins IRS-1, IRS-2, PI3K, and β-catenin. The ongoing development of proteomic strategies has helped to define functional roles for *O*-GlcNAc on a variety of proteins and disease states (Whelan and Hart, 2003).

O-GlcNAc modification is known to have functional roles in protein–protein interactions and degradation. For example, *O*-GlcNAc-modified Sp1 appears to inhibit its binding to TATA-binding protein-associated factor II 110 and decreases Sp1 transcriptional activity on certain promoters (Yang *et al*., 2001). The Rpt2 ATPase in the mammalian proteasome 19S cap is modified by *O*-GlcNAc and as the modification increases, the proteasome function in the degradation of substrates decreases (Zhang *et al*., 2003).

6. *O*-GlcNAc proteomics

The enormous dynamic range of protein expression and multiple posttranslational modifications on one protein combinatorially has made the study of cellular responses regulation very complex. As with phosphorylation, there are a number of proteomic approaches that have been developed to facilitate the characterization of *O*-GlcNAc (Greis and Hart, 1998; Gygi, 1999; Wells *et al*., 2002). The development of *O*-GlcNAc-specific antibodies has significantly increased the efficiency of identifying *O*-GlcNAc proteins. Before the use of these antibodies, galactosyltransferase labeling of *O*-GlcNAc with UDP[^{3}H]Gal was the primary method and still remains the standard for the detection and characterization of *O*-GlcNAc (Roquemore *et al*., 1994).

Affinity chromatography (i.e., CTD 110.6 or sWGA-sepharose) is often used to enrich fractions in order to reduce complexity for mapping sites. The use of β-elimination and Michael addition of an affinity tag to map phosphorylation sites has been adapted to map *O*-GlcNAc sites (Wells *et al*., 2002). The β-elimination and Michael addition of dithiothreitol (BEMAD), not only stabilizes the labile O-linkage during collision induced dissociation by LC-MS/MS mass spectrometry but also allows for further enrichment of deuterated DTT-modified peptides by thiol-Sepharose. Both phosphorylation and *O*-GlcNAc-modified sites may be simultaneously quantified with selective use of enzymes, in conjunction with differential labeling of DTT and deuterated DTT. Continued development of sensitive proteomic techniques is necessary to elucidate the biological significance

of the site-specific, dynamic, and global changes of *O*-GlcNAc, together with other posttranslational modifications in the proteome.

Short Specialist Review

Posttranslational modifications to plants – glycosylation

Yoram Tekoah
Ben-Gurion University of the Negev, Beer-Sheva, Israel

1. Introduction

Like other eukaryotic organisms, plants have glycoproteins with *N*- and *O*-glycans (see Article 64, **Structure/function of *N*-glycans**, Volume 6 and Article 65, **Structure/function of *O*-glycans**, Volume 6). *N*-Glycans are attached to asparagine residues and O-linked glycans are attached to hydroxyproline, serine, or threonine residues. Only a few plant proteins have been described with both types of glycans. Animal and plant cells have a similar capability to assemble protein subunits but the systems are not identical as far as posttranslational modifications (PTMs) are concerned (Houdebine, 2002). The complex *N*-glycans of plants differ markedly in structure from those of animals. They more closely resemble those of insects and molluscs (Figure 1). Plant *N*-glycans can be divided into two main types: high mannose type and complex type. The high mannose types are derived from the original $Man_9GlcNAc_2$ structure common to plant and animal glycans. The general formula $Man_{5-9}GlcNAc_2$ represents glycans that are not fully processed. The complex type glycans may contain an α-(1,3)-fucose (Fuc) linked to the proximal GlcNAc residue and/or a β-(1,2)-xylose (Xyl) residues attached to the α-linked mannose (Man) of the glycan core. This glycan type is named *paucimannosidic* – type *N*-glycan (Lerouge *et al*., 1998). In plants, these additional N-linked glycans are considered antigenic (Faye *et al*., 1993) and/or allergenic (van Ree *et al*., 2000). In various cases additional modifications such as additional mannose or GlcNAc sugars are found. Plant glycans are not found to contain sialic acid residues that are present in mammalian glycans.

2. N-linked glycans

The biosynthesis of N-linked high-mannose glycans in plants is identical to that in yeast and mammals and involves the en bloc transfer of the $Glc_3Man_9GlcNAc_2$ oligosaccharide from dolichylpyrophosphate to specific asparagine residues constitutive of the N-glycosylation sequences, Asn-X-Ser/Thr (where X is any amino acid

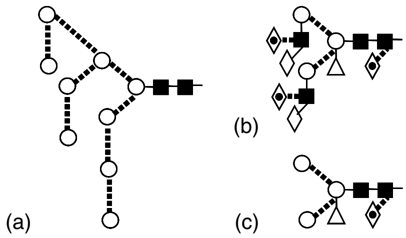

Figure 1 Diagrammatic representation of structures of various *N*-linked glycans found in plant glycoproteins. (a) High mannose type, (b) complex type, and (c) paucimannosidic type glycan. The symbols of the glycan structures are: mannose: clear circle; GlcNAc: dark square; galactose: diamond; fucose: diamond with a dot; xylose: triangle; |: 1–2 linkage; /: 1–3 linkage; –: 1–4 linkage; \: 1–6 linkage; solid line: β-linkage; dotted line: α-linkage

except Pro) in the nascent polypeptide chains. Once transferred onto the nascent protein and while the glycoprotein is transported along the secretary pathway, the oligosaccharide N-linked to Asn (*N*-glycan) undergoes several maturation steps involving the removal and the addition of sugar residues in the endoplasmic reticulum (ER) and the Golgi complex. The removal of glucose residues is achieved by glucosidase I and II in the lumen of the ER. This is then followed by transport of the protein to the Golgi. In the late Golgi apparatus, plant and mammalian *N*-glycan maturations are found to differ. In the Golgi, additional modification of the high-mannose glycans that are accessible to the various modifying enzymes that exist in the Golgi, is achieved to produce complex glycans. These modifications resemble the process found in mammalian cells. The process is initiated by the removal of four mannose residues by mannosidase I. It then continues by the attachment of a peripheral GlcNAc by GlcNAc transferase I (GlcNAcT-I) to the α-1–3-linked mannose attached to the central β-1–4-linked mannose. This is followed by the removal of two more mannose residues by mannosidase II, and attachment of a second peripheral GlcNAc residue. Only after the addition of at least one GlcNAc a β-1,2-xylose residue is transferred by a β-1,2-xylosyltransferase (β-1,2-XylT) to the β-linked mannose of the core. As an independent event, an α-1,3-fucose residue is added to the proximal GlcNAc of the chitobiose core by α-1,3-fucosyltransferase (α1,3-FucT) (Lerouge *et al*., 1998). These events occur in the medial and trans Golgi cistenae respectively (Fitchette-Laine *et al*., 1994). It is important to note that mammalian glycoproteins have not been reported to contain α-1,3-fucose or β-1,2-xylose residues. However, similar constituents and epitopes are reported on the glycoproteins of lower animals (e.g., molluscs, insects, and spiders) (Staudacher *et al*., 1999). In some cases, plant glycoproteins are found to be immunogenic when injected into mammals. It is likely that the α-1,3-fucose and β-1,2-xylose residues account for this immunogenicity, and the potential for inducing the allergenic characteristic of plants in mammals (Tekoah *et al*., 2004), although it is sometimes thought that the fucose alone is the main problematic epitope (Staudacher *et al*., 1999). In other cases, no glycan specific antibodies were produced in mice that were injected with plant produced antibodies (Chargelegue *et al*., 2000). After the addition of the second GlcNAc residue and the fucose and xylose substitutions, the glycan can be

either transported to the vacuole or can be further modified. The transport of such glycoproteins to the vacuole invariably results in the removal of the peripheral GlcNAc residues, because vacuoles contain *N*-acetylglucosaminidases (Lerouge *et al*., 1998). Similarly, high-mannose glycans that escaped the action of mannosidase I in the Golgi may be further trimmed since the vacuole contains also α-mannosidase. Thus, we can find that complex glycans on vacuolar proteins are rather small and have the structure (Xyl)Man_3GlcNAc(Fuc)GlcNAc. This structure, called *paucimannose*, can be found also in insects. In the case of hybrid type glycans one can encounter structures such as Man_4Xyl(Fuc)GlcNAc or Man_5Xyl(Fuc)GlcNAc. If the protein is not transferred to the vacuole but rather secreted, then the glycoproteins retain their peripheral GlcNAc residues because the cell wall has little or no *N*-acetylglucosaminidase activities. At this stage, the complex type *N*-glycans can be further processed by the addition of a terminal fucose residue by an α-1,4-fucosyltransferase (FucT) and a galactose residue by a β-1,3-galactosyltransferase (GalT) (Lerouge *et al*., 1998). This leads to a structure, Gal-β-1,3 (Fuc α-1,4) GlcNAc, known as *Lewis*^{a} (Le^a). This Le^a antigen that has been detected only in some plant proteins, is also found on cell surface glycoconjugates in mammalian systems and is usually involved in cell–cell recognition (Chen *et al*., 2005).

To date, peptide-N^4-(*N*-acetyl-β-glucosaminyl) asparagine amidase A (PNGase A) from almond emulsin is the only *N*-glycanase commercially available that is able to release N-linked glycans that contain α-1,3-core-fucose (Tretter *et al*., 1991). Since it is thought that α-1,3-core-fucose is an epitope involved in pollen and food allergy in addition to the β-1,2-xylose (Tretter *et al*., 1993; Wilson *et al*., 1998), it is most important to use PNGase A rather than peptide *N*-glycanase F (PNGase F) from *Flavobacterium meningosepticum* in order to ensure that all plant glycans have been released when studying glycoproteins from plants. An alternative is to release the glycans chemically with a procedure using hydrazine (Patel *et al*., 1993, see also Article 76, **Analysis of N- and O-linked glycans of glycoproteins**, Volume 6).

Glycans affect the physicochemical properties of a protein, including resistance to thermal denaturation, protection from proteolytic degradation, and solubility. It can also alter essential biological functions, such as immunogenicity, clearance rate, specific activity, and ligand–receptor interaction. The function of *N*-glycans on plant glycoproteins is to stabilize them against proteolytic degradation. Although a wide variety of glycans exist in plants, the function of complex glycans (as opposed to high-mannose glycans) is not understood. Studies showed that an *Arabidopsis* mutant (*cgl*) that lacks GlcNAc transferase I (GlcNAcT-I) and is unable to convert high-mannose glycans to complex glycans has no visible phenotype when grown under standard laboratory conditions (von Schaewen *et al*., 1993) unlike the case found in mammals (Ioffe and Stanley, 1994).

3. O-linked glycans

O-linked glycosylation can be found in amino acids that contain a hydroxy group (i.e., Ser, Thr, hydroxyproline (Hyp), and hydroxylysine). *O*-Glycans found in mammalian systems are usually linked to Ser or Thr residues of the polypeptide

backbone. These glycan structures can range from simple monosugars (Fuc, Glc, or GalNAc) to several sugars such as mucinlike oligosaccharides attached to core GalNAc linked to Ser/Thr residues. While N-linked glycans involve a single-step cotranslational addition of the N-linked oligosaccharide precursor on Asn residues followed by additional modifications in the ER and Golgi apparatus, O-glycosylation of Ser/Thr residues is a posttranslational multiple-step procedure in mammals. Like *N*-glycan maturation, *O*-glycans are transferred by glycosyltransferases from nucleotide-sugar donors onto *O*-glycans in the Golgi apparatus.

Very little information is yet available on mammalian-like *O*-glycans in plants (Faye *et al*., 2005). Some studies of O-linked glycans attached to Ser or Thr residues of plant glycoproteins have been reported. An O-glycosylated Ser residue with a single galactose was found in the cell wall glycoprotein extensin (Cho and Chrispeels, 1976). A similar monogalactosylation of Ser residues was found in proteins such as sweet potato sporamin (Matsuoka *et al*., 1995). Various proteins from rice have been shown to have mammalian mucin-type glycosylation (Mitsui *et al*., 1990; Kishimoto *et al*., 1999). In a study of glycosylation of therapeutic proteins expressed in plants, up to six proline/hydroxyproline conversions and variable amounts of arabinosylation (Pro/Hyp + Ara) were found in the hinge region of maize-expressed *h*IgA1 heavy chain (HC) (Karnoup *et al*., 2005). In some cases plants have been found to contain an additional O-linked *N*-acetylglucosamine (O-GlcNAc) similar to that found in mammalian proteins and is known as a key regulator of nuclear and cytoplasmatic protein activity (Love and Hanover, 2005).

4. Transgenic plants and glycosylation

Lately, it has been shown that plants can be used as a production system for recombinant mammalian proteins (Faye *et al*., 2005). The majority of therapeutic proteins require PTMs such as glycosylation to be effective. Nevertheless, if plants are to be used to produce mammalian proteins which are glycoproteins, they will usually be found to carry plantlike glycosylation that is usually highly immunogenic and potentially allergenic. In this case, it is most important to understand the structure of the glycans attached to the proteins to evaluate the potential use of these proteins (Tekoah *et al*., 2004). One of the attractive uses of transgenic plants is for the production of recombinant pharmaceuticals such as antibodies or lysosomal enzymes that are needed in large quantities (molecular pharming). Production in plants has various advantages such as the lowering of production costs of the therapeutic proteins compared to alternative methods. Projects are already under way to produce a number of mammalian proteins in plants, with clinical trials set to begin in the near future. Since glycosylation differs in plants and mammals, much work has been done recently and is still needed to overcome this drawback (Chen *et al*., 2005).

Several approaches can be used to avoid these potential problems. If mammalian proteins are produced in GlcNAcT-I-deficient mutant plants similar to those described by von Schaewen (von Schaewen *et al*., 1993) then all the glycans will be of the Man_5 $GlcNAc_2$ type, and such glycans will not be immunogenic. However, proteins containing mannose-terminating glycans will be rapidly cleared by the

mannose receptor of macrophage cells in mammalian systems. A second approach would be to eliminate (knockout) certain glycosidases and glycosyltransferases that can be problematic and add other specific mammalian glycosyltransferases. For instance, plant cells transformed with mammalian GlcNAcT-I, a mammalian Golgi enzyme, have been shown to function correctly in a plant cellular environment, and thus it should be possible to obtain plants that make *N*-glycans without xylose and with α-1,6-fucose on the proximal GlcNAc (Gomez and Chrispeels, 1994). The pathway for the synthesis of sialic acids does not exist in plants and therefore the production of glycoproteins that contain sialic acid residues would be more difficult. This would need to include enzymes to make this sugar, to attach it to cytidine monoshosphate (CMP). The protein to transport CMP-Sia across the Golgi cisternal membrane would have to be incorporated into the transgenic plants as well as a sialyltransferase. A third approach is to produce the mammalian proteins with carboxy-terminal signals such as amino acid sequences Lys/His-Asp-Glu-Leu (KDEL or HDEL) that cause the proteins to be retained in the ER. Proteins that have been modified in this way have been shown to accumulate to quite a large extent in the ER of leaves. Such proteins typically have high-mannose glycans similar to those of other ER residents (Ko *et al*., 2003; Tekoah *et al*., 2004). Plant systems have several advantages for the production of therapeutic proteins compared to animal systems, in addition to low cost of production. The easy scale-up, and the lack of animal pathogens, is not less important. Future studies will enhance our knowledge regarding the possibilities of "humanizing" plant glycosylation on therapeutic proteins.

5. Glycosylation in algae and production of therapeutic proteins

Very little is known about glycosylation in algae. The diversity of the various species of algae makes it an interesting alternative for production of therapeutic proteins. Furthermore, glycosylation can be similar to that of higher plants, such as is thought to be the case in the green algae *Chlamydomonas reinhardtii*. In other cases, totally different glycosylation patterns may exist, such as in the red algae *Porphyridium* sp. (Tekoah, unpublished data). Various studies have shown the potential of the production of such proteins in *C. reinhardtii* (Mayfield *et al*., 2003; Mayfield and Franklin, 2005). The benefits of utilizing algae for the production of therapeutic proteins are the same as in plants. In addition, the high growth rate, and the contained and controlled environment of growth and diversity of algae, can enhance these benefits. All this will not be feasible without the proper future study of glycosylation in algae that will help in the understanding of the glycosylation pathways, both in plants and algae, and help set potential goals for "humanization" of glycosylation.

6. Summary

The study of glycosylation in plants and algae has still to be fully elucidated. Plant genetic engineering can lead to the economical production of therapeutic

proteins, which are safe and a viable alternative to current methods of production in animal systems. Findings indicate the benefits that may arise from modifications of glycosylation of these proteins, using plant genetic engineering. But the importance of studying the glycosylation in therapeutic proteins to monitor the modifications of the glycans is important for ruling out potential harmful PTMs of glycans (Tekoah *et al*., 2004).

1. Introduction

Phosphorylation is one of the most prevalent and important intracellular protein modifications. It is estimated that at any given time approximately 30% of all proteins are phosphorylated (Hunter, 1998). The fast reversibility of protein phosphorylation makes it very attractive for regulating cellular processes as diverse as metabolism, signaling, and cell proliferation. Numerous amino acid residues can be phosphorylated including aspartic acid, cysteine, and histidine. However, major research efforts so far have been focused on serine, threonine, and tyrosine phosphorylation because these amino acid residues are the main target for phosphorylation in eukaryotes. In addition, they are chemically more stable and thus considerably easier to analyze (Yan *et al*., 1998). Phosphorylation analysis is composed of several steps: (1) the detection of a known phosphorylation site, (2) residue-resolved localization of (novel) phosphorylation sites, (3) monitoring changes in phosphorylation (relative quantitation), and (4) determining the degree of phosphorylation (absolute quantitation of phosphosylation stoichiometry).

Common strategies for the analysis of protein phosphorylation utilize radioactive phosphorus isotopes, phosphospecific or phosphorylation site specific antibodies, and/or mass spectrometry (MS). Each method has its advantages and disadvantages for phosphorylation analysis, which will be summarized in the following section of this article.

2. Radioactive labeling

A well-established method for the analysis of protein phosphorylation is the incorporation of the radioactive phosphorus isotopes ^{32}P or ^{33}P. In order to detect a particular phosphorylation site, this method is combined with phosphopeptide

mapping by two-dimensional thin layer chromatography (2D-TLC) or liquid chromatography (LC) followed by radioactivity measurements to identify the spots/fractions of interest (Yan *et al*., 1998). However, this approach requires that a detailed analysis of the different phosphopeptides is carried out in order to unambiguously correlate a spot/fraction with a particular phosphorylation site. Since the detection of radioactivity is quantitative this method is suitable for relative quantitation, but not necessarily for absolute quantitation as the initial amount of protein is not always known.

To utilize radioactive labeling for residue-resolved localization of phosphorylation sites, Edman degradation–based approaches have proven to be useful. After isolating and purifying the phosphopeptides by, for example, 2D-TLC or LC, the identity of the peptide is determined by MS. This is followed by Edman degradation where the peptide is sequentially hydrolyzed and the release of radioactivity during one particular cycle from the immobilized peptide can be correlated with the primary sequence as determined by MS prior to the Edman degradation. The sequence of events described above identifies the site of phosphorylation (Campbell and Morrice, 2002).

True "de novo" sequencing of phosphopeptides by Edman degradation is problematic as the Phenylthiohydantoin (PTH) derivative of phosphotyrosine is barely soluble (Aebersold *et al*., 1991) and phosphoesters of threonine and serine undergo β-elimination under the conditions used for Edman sequencing. This side reaction gives rise to numerous undefined products such that phosphoserine or phosphothreonine residues are often only assigned with ambiguity (Campbell *et al*., 1986; Dedner *et al*., 1988).

Radioactive labeling is very sensitive and well suited for in vitro phosphorylation assays. However, in vivo incorporation of the radioactive isotopes is not possible in the case of tissue samples or is very inefficient in the case of cell culture due to the presence of endogenous unlabeled adenosine triphosphate (ATP). Hence, to achieve a degree of in vivo phosphorylation that is sufficient for sensitive detection, very large amounts of radioactively labeled ATP are required such that other pleiotropic effects cannot be excluded.

3. Phosphospecific antibodies

Three different types of antibodies are used for protein phosphorylation analysis:

1. *Anti-phosphoamino acid antibodies:* Anti-phosphotyrosine antibodies were invaluable for the elucidation of phosphotyrosine-based mitogen and cytokine signaling. They can be used for profiling the global tyrosine phosphorylation state of a particular sample after 1D or 2D gel analysis (*see* Article 22, **Two-dimensional gel electrophoresis**, Volume 5; Figure 1b), and for the enrichment of tyrosine-phosphorylated proteins by immunoprecipitation (Pandey *et al*., 2000). Although antibodies are mainly used for proteins, a recent study showed that these antibodies are also applicable to the enrichment of tyrosine-phosphorylated peptides (Rush *et al*., 2005). The development of good anti-phosphoserine and anti-phosphothreonine antibodies has been less successful so far (Gronborg *et al*., 2002).

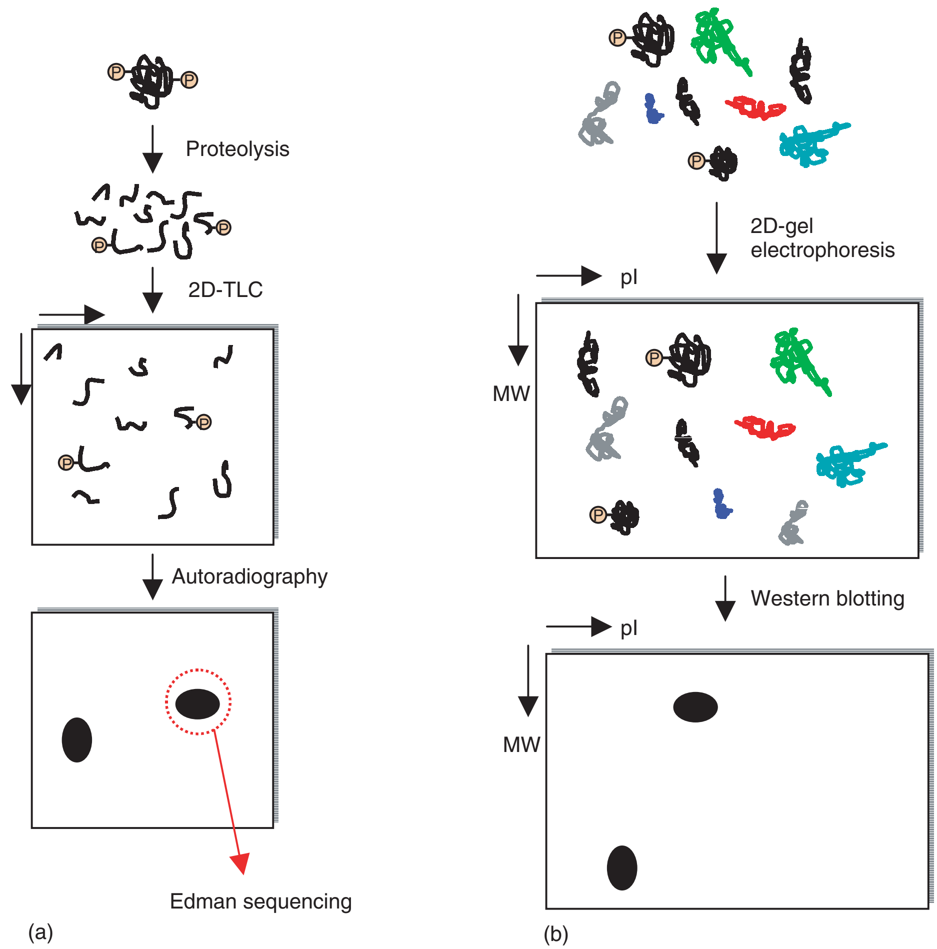

Figure 1 (a) A schematic portraying the radioactivity-based analysis of phosphorylated peptides involving proteolysis, two-dimensional thin layer chromatography (2D-TLC), and autoradiography to visualize the radioactively labeled peptides prior to Edman sequencing to determine the amino acid sequence. (b) A schematic for the identification of, for example, tyrosine-phosphorylated peptides using western blotting with anti-phosphotyrosine antibodies subsequent to two-dimensional gel electrophoresis (2D-GE). 2D-GE separates proteins in the first dimension on the basis of the isoelectric point (pI) and in the second dimension, on the basis of molecular weight

2. *Antibodies against phosphorylation consensus motifs:* These antibodies are raised against oriented peptide libraries mimicking particular phosphorylation consensus motifs (available from e.g., Cell Signaling Technology). They are a suitable compromise for serine and threonine phosphorylation motifs and can be used in a fairly broad context as well as for specific questions (Zhang *et al*., 2002a).
3. *Phosphorylation site–specific antibodies:* As antibodies can be the most sensitive, specific, and fastest way to detect a particular protein phosphorylation in complex protein mixtures, such as whole cell lysates, the use of these types of antibodies is becoming more widespread. However, localization of

the phosphorylation site by other means such as MS, Edman degradation with radioactive labeling is a requirement because the unbiased localization of novel phosphorylation sites using site specific antibodies is not possible.

Another advantage of antibodies is the semiquantitative nature of the Western blotting such that relative (semi-)quantitation is possible. However, absolute quantitation is impossible if one only uses phosphospecific antibodies. Other limitations of the use of antibodies stem from the fact that it is not always possible to raise antibodies against all phosphorylation sites and that specificities can be questionable in cases where multiple phosphorylation sites are found in close proximity.

4. Mass spectrometry

Mass spectrometry is very commonly used for the analysis of protein phosphorylation especially due to its improved sensitivity and speed as compared to many traditional biochemical methods such as Edman degradation. Another major advantage of MS is its versatility – that is, it can be used for any kind of phosphorylation analysis. If the identity of a protein and its phosphorylation sites are known, then directed mass spectrometric experiments can be performed in order to determine whether a particular site is phosphorylated or not as the mass-to-charge ratio of the expected proteolytic phosphopeptide can be calculated.

1. Relative quantitation of protein phosphorylation can be performed using stable isotope labeling approaches using metabolic, enzymatic, or chemical means to incorporate the label (Ibarrola *et al*., 2003; Oda *et al*., 1999). Alternatively, stable isotope-free methods can be used to monitor changes in the degree of phosphorylation after normalizing the raw data to account for run-to-run variations and variations in the starting amount of material (Ruse *et al*., 2002; Steen *et al*., 2005).
2. Absolute quantitation of the phosphorylation stoichiometry can be achieved by using either isotopically labeled internal standards (Stemmann *et al*., 2001), isotope labeling in combination with phosphatase treatment (Zhang *et al*., 2002b), or a completely stable isotope-free methods (Steen *et al*., 2005).

The true power of MS is its ability to sequence peptides in a second to subsecond timescale and to unambiguously localize phosphorylation sites down to the residue level in an unbiased manner (Figure 3a and b; Article 4, **Interpreting tandem mass spectra of peptides**, Volume 5). Different strategies have been devised to identify and analyze the phosphorylated peptides within a complex mixture such as proteolytic protein digests.

The most successful strategies for mass spectrometric analysis of protein phosphorylation is to utilize either selective enrichment of phosphorylated species utilizing, for example, generic antibodies (see above) or immobilized metal affinity chromatography (IMAC; see below) approaches (Figure 2) (Posewitz and Tempst, 1999) and/or utilize the characteristic fragmentations of phosphopeptides upon

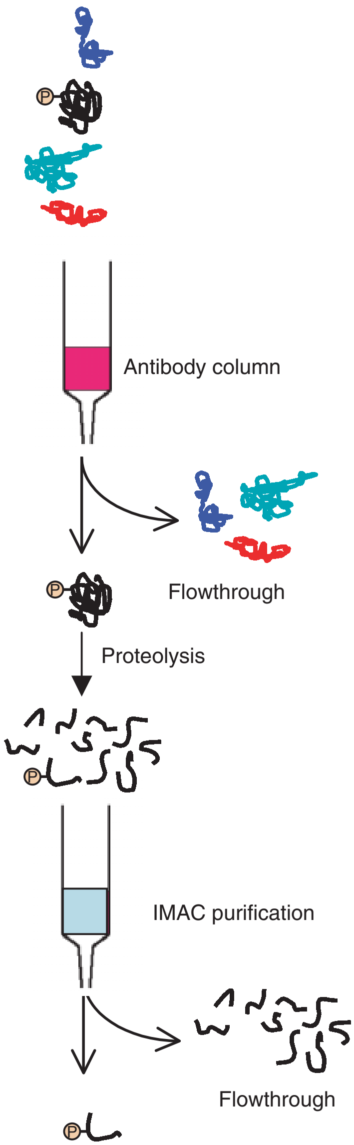

Figure 2 A general strategy using antibodies and immobilized metal affinity chromatography (IMAC) to enrich for phosphoproteins and subsequently phosphopeptides. Each of the enrichment steps can also be used separately

collisionally induced dissociation (CID) for so-called (constant) neutral loss and/or precursor ion experiments (Covey *et al*., 1991; Huddleston *et al*., 1993; *see also* Article 18, **Techniques for ion dissociation (fragmentation) and scanning in MS/MS**, Volume 5).

In general, it is always advisable to reduce the complexity of the sample as much as possible by enriching the protein(s) of interest or even the phosphorylated form(s)

of the protein(s) of interest using, for example, antibodies. However, it should be noted that quantitation of the phosphorylation stoichiometry is not possible if only the phosphorylated species (protein or peptide) is enriched. Following the enrichment of the protein(s) of interest, the sample is digested generating a complex mixture of peptides some of them being modified, that is, phosphorylated, but the vast majority being unmodified. The analytical challenge is to maximize the time spent on the analysis of the phosphopeptides and to minimize the time spent on the unmodified peptides. However, a bias against substoichiometric species of low abundance has to be expected when simple data dependent acquisition (DDA) routines are used for the acquisition of data since the peptides are selected for sequencing simply on the basis of the signal intensities of the peptide in the survey scan. This is less of a problem for samples of fairly low complexity, for example, single protein digests, as long as the number of peptides eluting off the LC column does not exceed the number of peptides that can be analyzed with these DDA routines. Thus, although a simple DDA experiment with a standard LC setup is valid as a first screen/first pass experiment, one must exercise caution. If phosphopeptides of very low abundance are expected or the sample is highly complex, such that at any given time during an LC/MS experiment more peptides elute than can be analyzed using DDA routines, numerous phosphopeptides might not be sequenced. Then, either enrichment protocols aimed at enriching the phosphopeptides or selective detection methods are advisable to efficiently utilize the valuable measuring time for analysis of the species of interest.

4.1. Selective detection

The phosphopeptide-specific mass spectrometric detection is based on characteristic fragmentations of phosphopeptides when fragmenting them in tandem mass spectrometers. For instance, in the negative ion mode (which is generally not suitable for peptide sequencing), a highly characteristic fragment ion at *m/z* −79 corresponding to PO_3^- is observable. In contrast, in the positive ion mode, a characteristic loss of H_3PO_4 (98 Da) is often prevalent for phosphoserine- and threonine-containing peptides, but is not commonly observed for tyrosine-phosphorylated peptides. The novel linear ion trap instruments (QTRAP or LTQ) are especially useful in utilizing these phosphopeptide-specific features on an LC-compatible timescale (Beausoleil *et al*., 2004; Le Blanc *et al*., 2003).

4.2. Selective enrichment

The most commonly used enrichment method is based on IMAC, which selectively binds phosphopeptides. Commercially available and in-house-made IMAC materials are commonly used and have all shown promising results. However, because of the mode of binding, it is expected that a certain number of acidic peptides, that is, aspartic acid and glutamic acid–rich peptides will be enriched as well. This problem of nonspecificity is more prevalent with highly complex samples (e.g., whole cell lysates) such that esterification of the carboxyl groups is recommended in those cases (Brill *et al*., 2004; Ficarro *et al*., 2002).

Other enrichment methods that are easily implemented are based on strong cation exchange (SCX) (Beausoleil *et al*., 2004) or strong anion exchange materials (SAX) (Nuhse *et al*., 2003). Ion exchange chromatography approaches utilize the low/high affinity of phosphopeptides to the respective ion exchange material. Both studies show impressive results using highly complex peptide mixtures as starting material. However, the binding/nonbinding of both the SCX and SAX approaches rely on the net charge of the peptide, that is, the amino acid composition. Thus, they are biased against certain subsets of peptides, for example, histidine-containing phosphopeptides in the case of SCX-based strategies (*see* Article 13, **Multidimensional liquid chromatography tandem mass spectrometry for biological discovery**, Volume 5).

If matrix assisted laser desorption/ionization (MALDI) is employed for the phosphopeptide analysis, then "hot" (dissociation-inducing) matrices such as α-cyano-4-hydroxycinnamic acid should be avoided as they lead to the loss of the phospho moiety from serine and threonine-phosphorylated peptides, reducing the signal intensity of species of interest, that is, the phosphopeptides (*see* Article 14, **Sample preparation for MALDI and electrospray**, Volume 5). Thus, the use of "cold" matrices such as dihydroxybenzoic acid are recommended. Also, the addition of nitric or phosphoric acid has shown to increase the ionization/detection efficiencies of phosphopeptides (Stensballe and Jensen, 2004). If a MALDI mass spectrometer without MS/MS capability is used for the MALDI analysis, phosphopeptides can be selectively identified in peptide mixtures by performing the MALDI MS analysis before and after phosphatase treatment of the sample. The phosphorylated species decreases in weight by 80 Da or multiples thereof upon enzymatic dephosphorylation (Figure 3c). However, for residue-resolved localization of the phosphorylation sites, additional MS/MS experiments on the species of interest are required.

5. Other methods

Instead of using generic antibodies against phosphoamino acid to profile the phosphorylation state of samples after 1D or 2D gel analysis, it is also possible to use a phosphospecific fluorescence dye called Pro-Q Diamond (Molecular Probes) (*see* Article 27, **Detecting protein posttranslational modifications using small molecule probes and multiwavelength imaging devices**, Volume 5). This reagent provides detection limits in the subpicomole range and is compatible with subsequent in-gel digestion and MS analysis protocols. Hence, more detailed analysis of the gel spots of interest is possible. Furthermore, the binding of the fluorescence probe can be used for quantitation up to 3 orders of magnitude (Steinberg *et al*., 2003).

6. Conclusion

The methods described above are only a small selection of a vast array of different strategies used for the analysis of protein phosphorylation. The aim of this tutorial is to give a brief synopsis of the most broadly applicable and promising detection

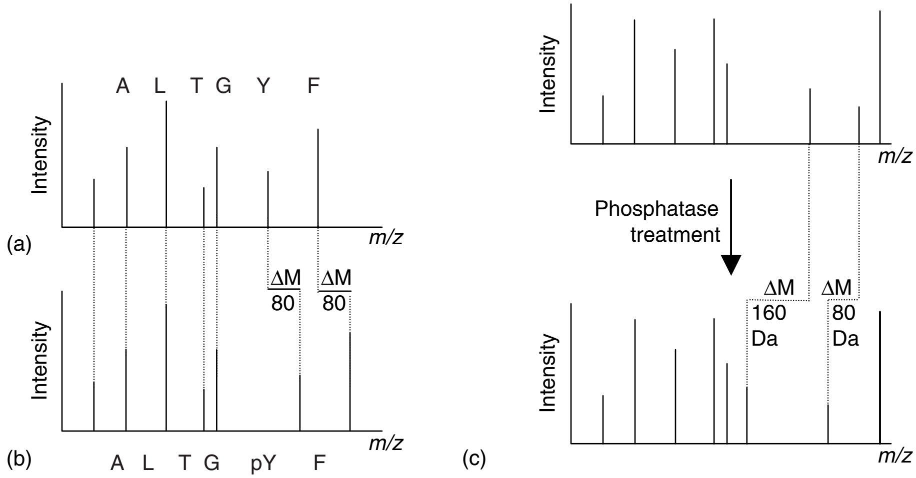

Figure 3 A schematic portraying how to localize phosphorylation sites using mass spectrometric phosphopeptide sequencing. Sequence-revealing peptide fragment ions derived from the phosphopeptide (b), that carry the phospho moiety and thereby localize the site of phosphorylation, are 80 Da heavier than the corresponding fragment ions in the product-ion spectrum of the unmodified cognate (a). (c) Identification of phosphopeptides within a peptide mixture based on the mass shift induced by phosphatase treatment of the peptides. The phosphopeptide masses decrease by 80 Da or multiples thereof depending on the number of phospho moieties enzymatically removed (here 2 and 1 phospho moieties, respectively)

and analytical methods, as well as their strengths and limitations. Experimental details should be explored in the references given. All of the methods have their particular advantages, such that the choice of method should be based on the question asked. An additional implication is that none of the methods is likely to provide a complete picture of the protein phosphorylation of a particular protein. For more comprehensive analysis, several methods should be combined as demonstrated by Vihinen and Saarinen (2000), and Chen *et al*. (2002) who combined five and more different strategies.

Basic Techniques and Approaches

Glycoproteomics

Miriam V. Dwek
University of Westminster, London, UK

Philippa Mills
University College London, London, UK

1. Background

It is now widely accepted that correct protein glycosylation is important for the normal function of many cellular and secreted proteins. Glycosylation has been shown to be necessary for many diverse aspects of protein function, for example, to ensure correct protein folding, to protect proteins from proteolytic attack, as recognition molecules for protein clearance from the serum, and as adhesion molecules. In parallel to the role of glycosylation in normal protein function, the number of examples in which changes occur to the glycosylation of proteins in disease expands. This "basic techniques" article considers some of the issues that would be faced by researchers interested in studying glycosylation of proteins as an adjunct to studying the proteome of a tissue or cell extract.

2. When might glycan analysis be indicated?

The inherent complexity of glycans, compared to that of a linear peptide chain, has meant that analysis of protein glycosylation has been largely neglected in proteomics. Nevertheless, there are circumstances in which glycan analysis might provide useful information as part of a proteomics study.

The standard approach for the identification of (glyco)proteins after separation of the proteome by 1D- or 2D-PAGE is generally by MALDI-MS (matrix-assisted laser desorption ionization mass spectrometry, *see* Article 2, **Sample preparation for proteomics**, Volume 5) fingerprint analysis. The separated proteins are digested, in-gel, with a protease such as trypsin, analyzed on a mass spectrometer (*see* Article 3, **Tandem mass spectrometry database searching**, Volume 5), and the resulting masses are compared with those generated by the theoretical digestion of protein sequences in databases (SWISSPROT and NCBI). Using this approach, a proportion of peptide masses may not be identified as originating from the proteolytic digestion of the protein. These difficulties in protein identification are often explained by the occurrence of posttranslational modifications such

as glycosylation and phosphorylation, which are not predicted by the majority of databases whose sequences, in the main, have been determined from the characterization of cDNAs. These "modified" peptides are often ignored when the sole interest is to identify the protein. Computational tools, such as FindMod, PeptIdent, and Peptide-Mass (**http://www.expasy.ch/tools/**) can calculate the difference between the observed and predicted masses giving a useful insight into the types of possible modifications that may have occurred to the protein. The complexity of protein glycosylation, however, has precluded its inclusion in the majority of database search engines with many only considering the addition of single O-GlcNAc residues. In the case of N-linked glycans, the consensus sequence Asn-Xaa-Ser/Thr (where Xaa is any amino acid other than Pro) allows putative identification of N-linked glycosylation sites. No similar sequence has been determined for O-linked glycosylation and the assumption that is generally made is that any Ser/Thr residue is potentially occupied by O-linked glycans, although an increase in Pro has been observed close to Thr O-link glycosylation sites. To address this matter, three different nine-residue peptides were used to evaluate the ability of recombinant GalNAc transferases to produce glycosylated peptides. From these data, it has been suggested that extended beta-like substrate conformations were favored for successful enzyme–substrate binding, suggesting that these regions of peptides are of some importance when trying to predict occupied O-linked glycosylation sites (Kirnarsky *et al*., 1998). Another approach to identifying likely O-link glycosylation sites has emerged; this utilizes a neural network algorithm and incorporates into an O-glycbase database, which provides free access and information regarding the type of glycan, the glycosylation site, species from which the glycoprotein was derived and so on. The database can be found at **http://www.cbs.dtu.dk/databases/OGLYCBASE/Oglyc.base.html**

3. Staining 2D-PAGE gels to identify glycosylated proteins

A simple starting point to determine whether or not a protein is glycosylated is to use the periodic acid-Schiff (PAS) stain. In this procedure, the gel is incubated in the presence of periodic acid (this oxidizes hydroxyl groups; and converts hydroxyl and amino groups to aldehydes) the aldehydes are then reacted with Schiff reagent (fuschin–sulfuric acid) to give a pink-red colored product. The PAS stain is sensitive to approximately 0.1 μg of protein. Combining the periodic acid reaction with fluorescent dye technology enables the detection of glycoproteins at nanogram sensitivity (Hart, 2003). One of the advantages of using this approach for detection of glycosylated proteins is that it allows the gel to be stained first for glycoprotein detection and later with a "total" protein stain such as Coomassie brilliant blue, silver nitrate, or Sypro ruby. An "overlay" can be produced to allow the identification of glycosylated proteins that may be subjected to further analysis.

4. On-membrane analysis of protein glycosylation

Proteins separated by 2D-PAGE can be transferred to inert membranes, usually made of either nitrocellulose or polyvinylidene difluoride, by a process known

as *Western blotting* (Towbin, 1979). The glycosylation of the proteins can then be examined by detecting the monosaccharides that are present by using carbohydrate-binding proteins, for example, lectins, or antibodies. The sensitivity of detection of glycan residues may be enhanced to nanomol concentrations by the use of biotin conjugated lectins and/or antibodies using streptavidin-horse radish peroxidase, to produce either a colored substrate or a light reaction. Useful data can be obtained with this approach to glycan analysis, particularly when a variety of lectins are used in series.

5. Release of N-linked glycans

Most of the methods for detailed analysis of N-linked glycans involve the removal of the glycan moiety from the protein backbone first, although there have been recent reports of analysis of intact glycoproteins after separation by 2D-PAGE (Emmett, 2003; *see also* Article 76, **Analysis of N- and O-linked glycans of glycoproteins**, Volume 6). For a glycan analysis strategy to be successful, the protein spot of interest would normally be clearly visible on a Coomassie blue stained gel (i.e., there would be microgram quantities of protein available); full structural analysis is not currently achievable using protein spots detected by silver nitrate or fluorescent dyes, although glycan "fingerprinting" may still be achievable depending on the extent to which the protein is glycosylated.

The most frequently used approach for glycan release is endoglycosidase digestion and several enzymes are commercially available (Harvey, 2001). The most widely used is PNGase-F (peptide *N*-glycosidase F). Enzymatic treatment is favored over chemical methods, such as hydrazinolysis or β-elimination, for the release of N-linked sugars because the glycans are less extensively modified and the protein can also be recovered intact (Harvey, 2001). Various strategies have been developed for in situ enzymatic release of N-linked glycans after separation of the individual glycoforms (Küster *et al*., 2001). Protocols involve the release of the glycan moiety from the protein either directly from excised gel spots or after electroblotting of the glycoproteins onto polyvinylidene difluoride membranes.

6. Release of O-linked glycans

While the techniques for the analysis of N-linked glycans released from glycoproteins are becoming routine, the same is not true for the analysis of O-linked glycans. Unfortunately, there is no enzyme that efficiently releases all O-linked oligosaccharides from the polypeptide backbone; instead, chemical methods such as hydrazinolysis and, more usually, nonreductive β-elimination (Harvey, 2001) or trifluoromethanesulfonic acid (Edge, 2003) are employed (*see* Article 76, **Analysis of N- and O-linked glycans of glycoproteins**, Volume 6).

7. Glycan analysis

As mentioned above, glycan analysis is usually only attempted for glycoproteins that are available in microgram quantities. Once released, various analytical

techniques are available for the characterization of carbohydrate structures. These include chromatography, electrophoresis, and mass spectrometry (MS). In order to improve sensitivity of detection, prior derivatization is required for the majority of these analytical procedures (Lamari *et al*., 2003; Harvey, 1999).

MS has now reached a level of sensitivity in which the study of glycoproteins and the attached oligosaccharide structures can be undertaken on proteins separated by gel electrophoresis. While the advanced "soft ionization" techniques of fast-atom bombardment (FAB), electrospray ionization (ESI), and MALDI permit the analysis of intact polymer units (oligosaccharide, polypeptide, or glycopeptide), full structural characterization of a glycoprotein or glycopeptide also requires determination of branching, linkages, and configurations and identification of same-mass sugar isomers of glycans (i.e., microheterogeneity). Using a combination of 2D-PAGE with MALDI-TOF it is possible to determine the macroheterogeneity, that is, the variation in different N-linked glycans that occupy a single glycosylation site (Mills *et al*., 2001). This technology coupled with site-directed mutagenesis enables studies to be performed to address the topic of glycan function at particular glycosylation sites. The ionization technique of MALDI-MS is arguably the most sensitive of the "soft ionization" techniques at least for simple mass analysis and is ideally suited to carbohydrate analysis, because, unlike many other forms of MS, spectra can be obtained from unmodified glycans (Harvey, 2001). MALDI ionization yields very few fragment ions and therefore is the preeminent technique for screening molecular ions, permitting simple and rapid mass analysis of glycans. Since N-linked glycans are synthesized by a well-defined pathway, an accurate mass measurement will generally permit prediction of the structure. To obtain high-quality mass spectra of the released oligosaccharides, it is essential that all compounds other than the analyte, such as buffers and salts, are removed (Harvey, 2001).

Microheterogeneity, that is, subtle differences in glycan branching or bonding (anomericity) will need to be investigated by combining several techniques, including exoglycosidase digestion (Harvey, 2001), analysis of hydrolysates by gas-chromatography electron impact (EI)-MS or FAB-MS, and tandem mass spectrometry. A recent review discusses the available mass spectrometric techniques for the ionization and fragmentation of oligosaccharides and computer-based approaches for interpretation of oligosaccharide product-ion mass spectra (Zaia, 2004). There are a limited number of Web-based Bioinformatic analysis tools that enable the interpretation of sugar mass spectrometric data. They include GlycoMod (**www.expasy.ch/tools/glycomod**) and GlycoSuiteDB (**http://tmat.proteomesystems.com/glycosuite/**).

8. Summary

N-linked glycan analysis can be undertaken as an adjunct to 2D-PAGE and mass spectrometry in proteomics strategies with relative ease but more detailed analysis of structures, particularly O-linked glycans, often requires a variety of different analytical tools.

Basic Techniques and Approaches

Mass spectrometry

David J. Harvey
University of Oxford, Oxford, UK

1. Introduction

Analysis by mass spectrometry involves the production of gas-phase ions from the analyte and the measurement of their mass-to-charge ratio (*m/z*) by their movement in electric or magnetic fields. Although the technique has its origins in the late nineteenth century, it was not until the late 1980s that satisfactory methods had been developed for producing ions from the large biopolymers such as proteins, glycoproteins, and nucleic acids. In order to exploit these ionization techniques, there has been a move away from traditional magnetic sector instruments to more modern methods for separation and measuring ions such as time-of-flight (TOF) instrumentation.

2. Ionization techniques

2.1. *Electron impact (EI) and chemical ionization (CI)*

Early techniques, suitable only for volatile organic molecules with masses up to about 1000 Da, involved bombarding the molecules, in the vapor phase, with beams of electrons (electron-impact (EI) ionization) to produce "odd-electron" ions of the type $M^{+\cdot}$, where the charge originates from the removal of an electron. Ions of this type are unstable and dissociate into fragments to produce the characteristic mass spectrum. The technique, coupled with gas chromatography and specific derivatization reactions, is used for the analysis of monosaccharides in experiments designed to identify the constituent sugars (Merkle and Poppe, 1994) of protein-linked carbohydrates and for determinations of linkage position (Hellerqvist, 1990). More stable "even-electron" molecular ions of the type $[M + H]^+$ can be produced by chemical ionization (CI), where the electron beam first ionizes a reagent gas such as methane, *iso*-butane, or ammonia to produce species such as CH_5^+ or NH_4^+, which then transfer a proton to the analyte with little excess energy.

2.2. *Fast-atom bombardment (FAB)*

One of the most important developments for the analysis of larger organic molecules occurred in the early 1980s with the introduction of fast-atom bombardment (FAB)

ionization (Barber *et al*., 1981). In this technique, the sample, often derivatized to a hydrophobic form, is dissolved in a liquid with a low vapor pressure, such as glycerol, and bombarded with a stream of atoms generated from an inert gas, or with ions such as Cs^+. The result is a beam of even-electron ions from a target that does not require heat, both conditions that are conducive to the production of stable molecular ions. Molecules with masses of up to about 10 000 Da can be ionized. The most suitable matrix for glycan ionization appears to be a mixture of glycerol and thioglycerol. The technique was used extensively in the 1980s for analysis of carbohydrates (Dell, 1987), particularly N-linked glycans, as it produced both abundant molecular ions and fragments. However, low sensitivity, caused by a high background from matrix ions, together with a requirement for derivatization, usually by permethylation, has resulted in this technique now being mainly of historical interest.

The real breakthrough in mass spectrometry for proteomics occurred in the late 1980s with the development of two ionization techniques, matrix-assisted laser desorption/ionization (MALDI) (Karas and Hillenkamp, 1988) and electrospray ionization (ESI) (Fenn, 1993), techniques that are both capable of ionizing molecules with masses in excess of 1 000 000 Da.

2.3. Electrospray ionization

The electrospray ion source works at atmospheric pressure and consists of a stainless steel or metalized silica capillary held at a high potential, typically about 3 kV, and placed a few millimeters from a counterelectrode (Figure 1). A solution of the sample flows through the capillary and charged droplets emerge into the ion source where they meet a counterflow of warm nitrogen gas, sometimes known as a curtain gas, to vaporize the solvent. As the droplet diameter decreases, a point is reached where electrostatic repulsion causes it to disintegrate into smaller droplets. The process continues until only ionized sample molecules remain. These are sampled by a sampling cone placed off-axis or orthogonal to the solvent flow and introduced into the mass spectrometer. Typical solvents are mixtures of water and either methanol or acetonitrile; pure water or nonpolar organic solvents are less effective. Traces of acetic or formic acid can be added to the sample solution to promote protonation. Other additives such as metal salts can be used to

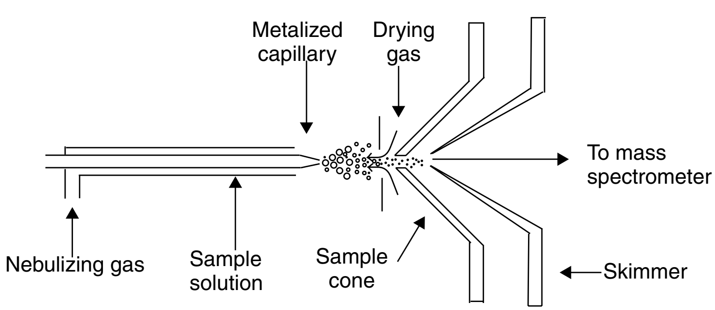

Figure 1 Electrospray ion source

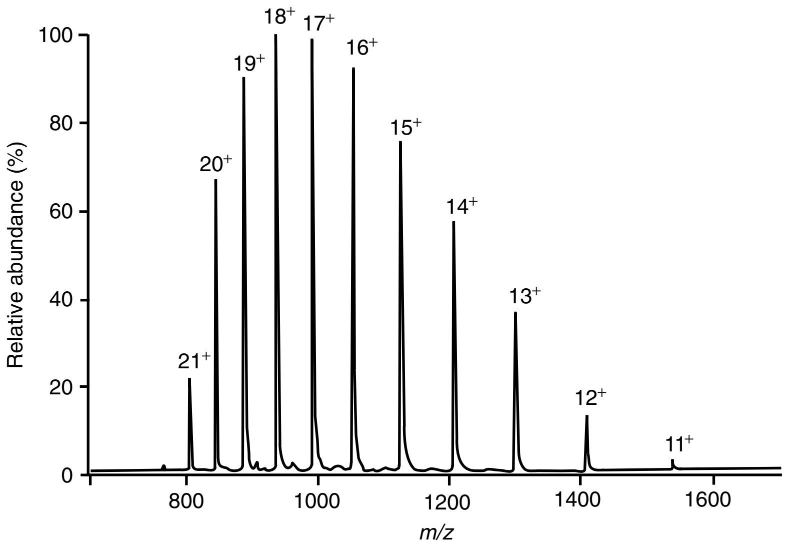

Figure 2 Electrospray spectrum of a protein

produce $[M + Metal]^+$ ions or to promote negative ion formation. Efficiency can be improved by use of a coaxial nebulizing flow of nitrogen around the spray, a technique known as ion spray.

Unlike most other ionization methods, electrospray ionization produces multiple-charged ions of the type $[M + nH]^{n+}$ or $[M - nH]^{n-}$, typically one charge for each kilodalton in mass for an average protein, thus allowing most proteins to produce an array of ions with *m/z* values within the range of most mass spectrometers (Figure 2). As many pairs of peaks are available for molecular weight calculations, an extremely accurate measurement of the mass can be obtained, usually better than 0.01%.

Carbohydrates are amenable to electrospray ionization and can be induced to produce a variety of ions, depending on the conditions. Neutral carbohydrates produce $[M + H]^+$, $[M + Na]^+$, and various doubly charged ions depending on whether the solvent contains an excess of protons or sodium ions. However, the larger glycans are not efficiently ionized. Stronger signals can be obtained in the negative ion mode, particularly from acidic glycans that contain sialic acid or sulfate, and more highly charged ions can form if several acid groups are present. Strong signals from neutral glycans can be obtained in the presence of a proton scavenger such as Cl^- or, particularly, NO_3^-.

2.4. *Matrix-assisted laser desorption/ionization (MALDI)*

In this technique, the sample is cocrystallized with a UV absorbing matrix and ionized with a laser, usually operating in the UV range (Figure 3). Ions are extracted with a high potential (in the order of 20 kV) and accelerated into the

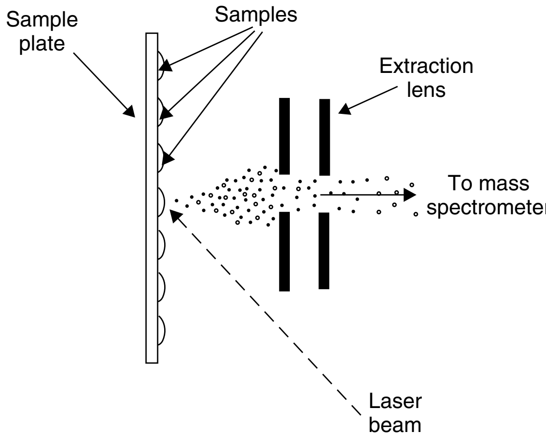

Figure 3 MALDI ion source

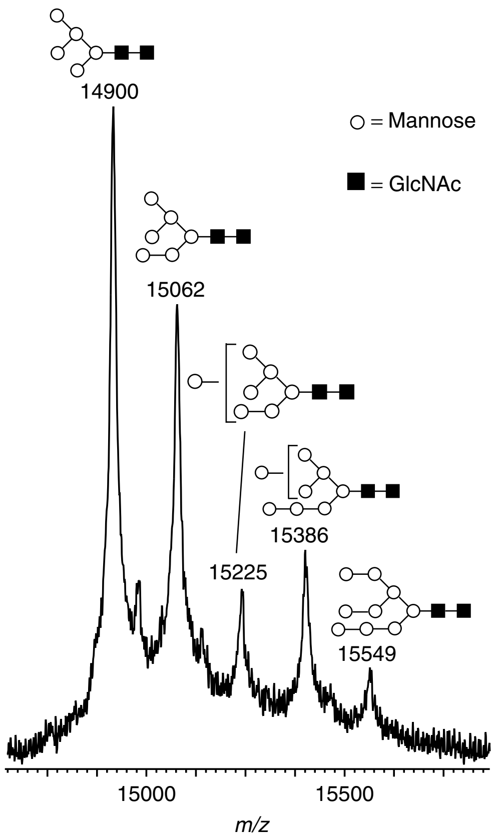
mass spectrometer. The purpose of the matrix is to dilute the sample and absorb the laser energy for transmission to the sample, but the exact mechanism by which this occurs is, as yet, unclear. Unlike electrospray ionization, the main products from proteins and glycoproteins are singly charged ions such as $[M+H]^+$, $[M-H]^-$, or $[M+Na]^+$ (Figure 4), but carbohydrates give almost exclusively $[M+Na]^+$ ions.

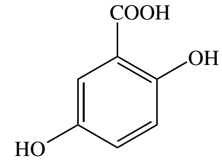
Various matrices are available; some of the most popular are listed in Table 1.

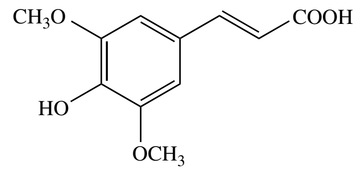
The laser energy is often sufficient to cause fragmentation, either within the ion source region (in-source decay (ISD)) or after the ion source (postsource decay (PSD)). A variation of MALDI is surface-enhanced laser desorption/ionization (SELDI) (Merchant and Weinberger, 2000) in which the laser target is a surface designed for adsorption of specific analytes such as peptides. MALDI is ideal for the ionization of carbohydrates (Harvey, 1999); however, as with electrospray, the sensitivity is not as high as that for peptides because the latter compounds are easily protonated. Nevertheless, carbohydrates can be derivatized with groups that either contain a charged function or that can readily be protonated or deprotonated. In order to achieve high sensitivity, it is essential to use clean samples from which contaminants such as salts, buffers, and antioxidants have been removed. Suitable methods are adsorption onto membranes (Börnsen, *et al*., 1995) or the use of various resins, often packed into small pipette tips (*see* Article 14, **Sample preparation for MALDI and electrospray**, Volume 5).

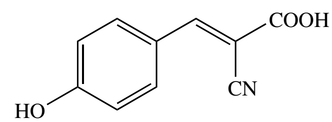
2.5. *Mass spectrometers*

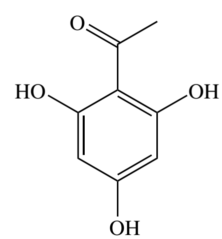
There are many techniques for analyzing ions depending on their mass and method of production. Early instruments used magnetic fields to deflect ions according to their *m/z* values and, later, instruments with combined electrostatic and magnetic fields were developed in order to provide high resolution and accurate mass measurements for the determination of ionic composition. These analyzers required a continuous beam of ions, but highest masses were limited by magnet size to about

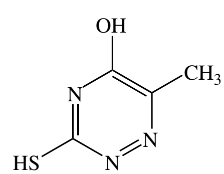


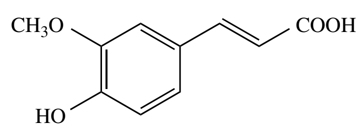












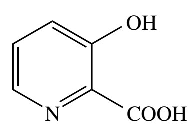


Figure 4 Typical MALDI mass spectrum of a glycoprotein

100 000. They were used extensively for EI, CI, and FAB studies. Quadrupole analyzers were a development of the 1970s. These instruments separated ions by a combination of direct and oscillating electric fields applied to four concentric rods (Figure 5). Again, continuous beams were required and, although relatively cheap, lightweight, and convenient to control with computers, upper mass limits and resolution were limited to a few thousands (*see* Article 8, **Quadrupole mass analyzers: theoretical and practical considerations**, Volume 5).

Time-of-flight (TOF) instruments (*see* Article 7, **Time-of-flight mass spectrometry**, Volume 5), (second analyzer in Figure 6), on the other hand, have no theoretical upper mass limit and are sensitive because all ions can potentially reach the detector; with magnetic sector and quadrupole instruments that scan the mass range, most ions are discarded. Modern instruments produce resolutions approaching those provided by double-focusing magnetic sector spectrometers. TOF instruments require a pulsed ion beam, such as that from a MALDI ion source, and measure *m/z* values by timing ions transmitted through a flight tube typically about 1 m in length. High-resolution measurements and focusing of PSD ions is achieved by reflecting the ions with an ion mirror or reflectron. Two other

Table 1 Common matrices for MALDI mass spectrometry

Matrix	Molecular weight	Analyte	Structure
2,5-Dihydroxybenzoic acid (DHB)	154.1	General, particularly sugars

6-Aza-2-thiothymine (ATT)	143.2	Gangliosides	
Ferulic acid	194.2	Glycoproteins	
3-Hydroxypicolinic acid (HPA)	139.1	Oligonucleotides	

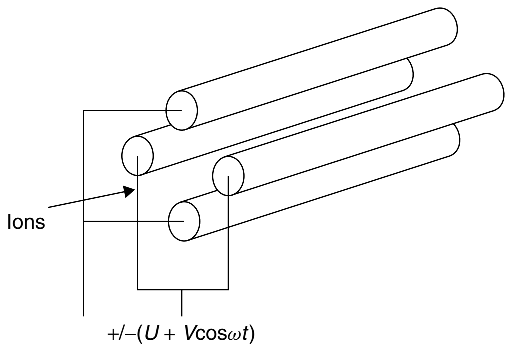

Figure 5 Quadrupole mass analyzer

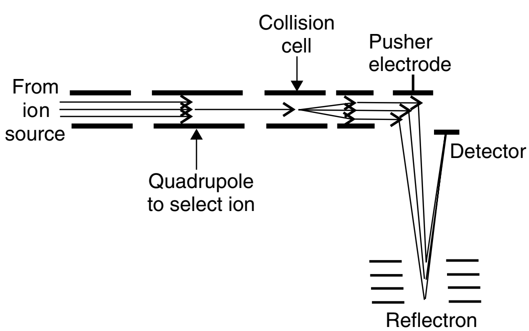

Figure 6 Q-Tof mass spectrometer

analyzers of interest are ion traps (*see* Article 9, **Quadrupole ion traps and a new era of evolution**, Volume 5) and Fourier transform ion-cyclotron resonance (FT-ICR) instruments (*see* Article 5, **FT-ICR**, Volume 5), both of which can trap ions and perform successive stages of fragmentation. The latter instruments are capable of very high resolution.

Analyzers can be connected in series in order to obtain fragment ions from a selected parent (*see* Article 10, **Hybrid MS**, Volume 5). The parent ion is selected from a mixture by using the first analyzer in a static condition, ions are fragmented in a relatively high-pressure region of the instrument, and the fragments are analyzed by a second analyzer. One of the most popular instruments of this type for proteomics is the Q-Tof tandem instrument that contains a quadrupole analyzer for initial ion selection, a collision cell, usually filled with argon to fragment the ions by collision, and a TOF analyzer to mass-measure the products at high sensitivity (Figure 6). Ionization usually employs an electrospray ion source although MALDI-Q-Tof instruments have recently been developed (Krutchinsky, *et al*., 1998). Ion trap and triple quadrupole instruments are also commonly found, the latter producing results similar to that of the Q-Tof instrument but at lower sensitivity because the third quadrupole is a scanning analyzer.

2.6. Uses of mass spectrometry for carbohydrate analysis

Both ESI and MALDI are able to produce spectra from glycoproteins but the resolution is usually not sufficient to resolve glycoforms for any but the smaller molecules, and then only those with single glycosylation sites (Figure 4). Glycans are, thus, usually removed either chemically (e.g., hydrazine) or enzymatically with endoglycosidases such as protein-*N*-glycosidase F (PNGase F) prior to structural analysis (*see* Article 76, **Analysis of N- and O-linked glycans of glycoproteins**, Volume 6). Site occupancy, however, can often be determined by cleaving the glycoprotein with a protease, such as trypsin, in order to localize a specific glycosylation site to a small glycopeptide. Mass spectrometric analysis of such glycopeptides can reveal the glycoforms at that site, and the carbohydrate compositions can be determined from their masses obtained by subtraction of the peptide mass, if the sequence is known. N-link site occupancy can be determined by cleaving the carbohydrate with PNGase F and measuring the mass of the residual peptide because this amidase leaves aspartic acid, which is one mass unit heavier, in place of the original asparagine.

Carbohydrates attached to glycoproteins contain only a few mass-different monosaccharides (Table 2). Consequently, it is relatively easy to deduce the

Table 2 Residue masses of common monosaccharides

Oligosaccharide	Residue formula	Residue mass
Deoxypentose	$C_5H_8O_3$	116.047 116.117
Pentose	$C_5H_8O_4$	132.042 132.116
Deoxyhexose	$C_6H_{10}O_4$	146.058 146.143
Hexose	$C_6H_{10}O_5$	162.053 162.142
Hexosamine	$C_6H_{11}NO_4$	161.069 161.158
HexNAc	$C_8H_{13}NO_5$	203.079 203.195
Hexuronic acid	$C_6H_8O_6$	176.032 176.126
N-Acetyl-neuraminic acid	$C_{11}H_{17}NO_8$	291.095 291.258
N-glycoyl-neuraminic acid	$C_{11}H_{17}NO_9$	307.090 307.257

Top figure = monoisotopic mass (based on C = 12.000000, H = 1.007825, N = 14.003074, O = 15.994915); Lower figure = average mass (based on C = 12.011, H = 1.00794, N = 14.0067, O = 15.9994).
Masses of intact glycans can be obtained by addition of the residue masses plus the figure for the terminal group (H_2O, 18.011 (monoisotopic) and 18.0153 (average)).

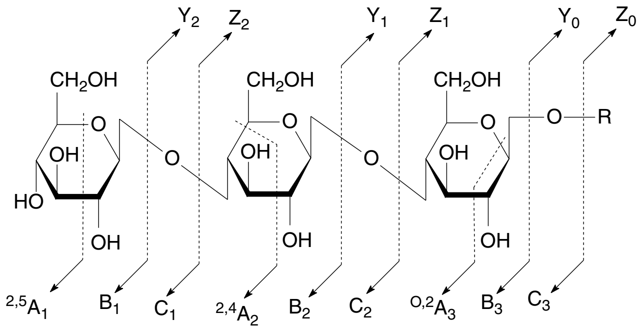

Figure 7 Nomenclature for describing fragment ions from carbohydrates

composition of these carbohydrates in terms of their isobaric monosaccharide composition by means of a single mass measurement. Mass spectrometry is not, however, able to distinguish isomers by this means; in order to achieve this, some chromatographic method of isomer separation, such as on-line high-performance liquid chromatography (HPLC) must be employed. Fine structural details are traditionally determined with the aid of exoglycosidases, with the products monitored either by HPLC after fluorescent labeling, or by MALDI MS.

With the advent of instruments such as the Q-Tof tandem mass spectrometer, fragmentation is assuming greater importance. Carbohydrates give mainly two types of fragment ions: glycosidic fragments where cleavage occurs between the sugar rings and which provides information on sequence and branching, and cross-ring fragments that provide information on linkage. Fragment ion nomenclature is as proposed by Domon and Costello (1988), and is outlined in Figure 7. $[M + H]^+$ ions give almost exclusively glycosidic fragment ions but $[M + Na]^+$ ions produce more complicated spectra with both glycosidic and cross-ring fragment ions. It has recently become evident that fragmentation of $[M - H]^-$ or $[M + X]^-$ ions, where X is a proton scavenger such as NO_3^-, produces much more informative spectra than fragmentation of positive ions. For N-linked glycans, for example, they produce fragments that reveal specific structural details such as individual antenna composition and the presence of a bisecting GlcNAc residue.

With the recent development of more sensitive instrumentation, better means of producing ions, and efficient coupling of contrasting techniques such as HPLC and Q-Tof mass spectrometry, the analysis of carbohydrates will increasingly depend on these technologies in the coming years.

1. Introduction

Sequence analysis has shown that nearly 70% of proteins carry the N-glycosylation sequon and that a further 10% can become O-glycosylated. The majority of proteins are therefore potentially glycosylated (Apweiler *et al*., 1999), and the analysis of the associated glycans is essential in their complete structural characterization. Unlike nucleic acids or proteins, both of which have linear sequences, most of the glycans attached to glycoproteins are branched structures with various position and linkage isomers. High resolution–separation techniques, which are often used concurrently, are required to characterize these diverse structures. Glycoproteins generally consist of a mixture of glycoforms in which a range of different sugars are present at each glycosylation site. In addition, some glycoproteins contain glycosylation sites that are variably occupied. Few glycoproteins have been fully characterized, although some have undergone extensive analysis (Takeuchi *et al*., 1988; Parekh *et al*., 1989; Rudd *et al*., 1997). In practice, it is possible to use the techniques described here to identify the majority of the glycans. Increasingly, techniques are becoming available for the analysis of the glycosylation of intact glycopeptides (Harvey, 2001; Iwase *et al*., 2001; Harvey, 2003). Monitoring the glycosylation of proteins and disease-associated alterations or determining the effect of alterations in the activity of glycan processing enzymes on glycosylation profiles is now a realistic proposition. Changes in glycosylation have been described in cancer (Litynska *et al*., 2000; Hakomori, 2001; Peracaula *et al*., 2003a,b; Callewaert *et al*., 2004; Ohyama *et al*., 2004), congenital enzyme deficiencies (Butler *et al*., 2003), autoimmune diseases (Parekh *et al*., 1985), and in various tissues of knockout mice in which genes for specific enzymes have been deleted (Furukawa *et al*., 2001; Sutton-Smith *et al*., 2002; Kui Wong *et al*., 2003). Glycosylation changes

may provide disease markers (Parekh *et al*., 1985) and give insights into disease pathogenesis (Malhotra *et al*., 1995).

2. Techniques

2.1. *Glycan release*

Figure 1 shows an overall strategy for glycan analysis. The most widely used technique for releasing N-linked glycans involves peptide-*N*-glycanase F (PNGaseF). This enzyme (EC 3.5.1.52) is an asparagine amidase, which cleaves the linkage between the core GlcNAc and the asparagine residue on the protein, releasing all classes of N-linked glycans (Kuhn *et al*., 1994) with the exception of those containing a fucose α 1–3 linked to the core GlcNAc (Altmann *et al*., 1995), which occur frequently in plant glycans. Glycans containing this α 1–3 linked fucose can however be released by the enzyme peptide-*N*-glycanase A used in conjunction with trypsin (Navazio *et al*., 2002; Ko *et al*., 2003; Tekoah *et al*., 2004). Alternatively, endoglycosidases that cleave N-linked glycans between the two core GlcNAcs can be used. Suitable enzymes include endo-H, which specifically cleaves oligomannose and hybrid N-links (Robbins *et al*., 1981), or endo-$F_{1,2\&3}$ (EC 3.2.1.96), which cleave oligomannose and hybrid, oligomannose and biantennary, bi- and triantennary structures respectively (Waddling *et al*., 2000). Enzymatic release has been demonstrated to release sugars efficiently, particularly from denatured proteins, and may be used to release N-linked glycans from individual glycoproteins separated by SDS-PAGE (Küster *et al*., 1997). Figure 2 shows the NP-HPLC profiles of N-linked glycans released by PNGaseF from the heavy chain, J chain, and secretory component (SC) of secretory IgA.

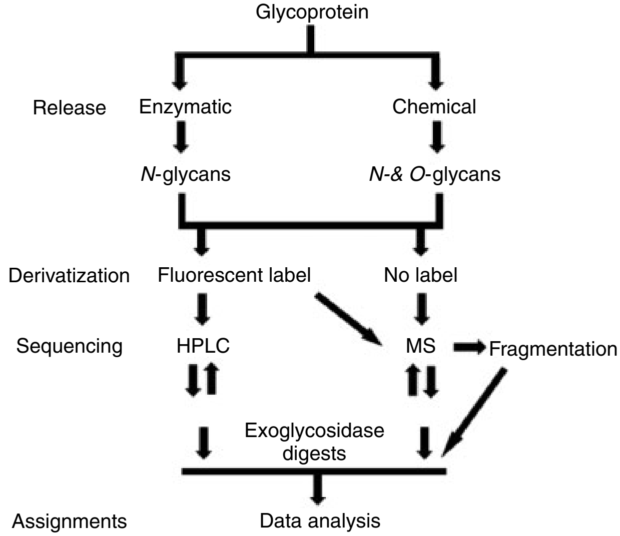

Figure 1 Diagram of a glycan analysis scheme using HPLC and mass spectrometry

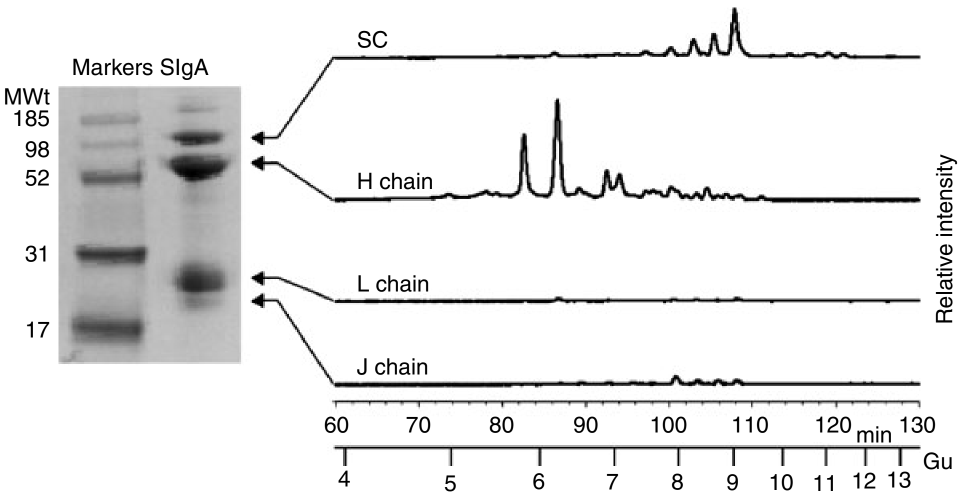

Figure 2 Secretory IgA (from human colostrum) was separated into secretory component (SC), heavy chain (H chain), light chain (L chain), and joining chain (J chain), on 10% BisTris SDS-PAGE after reduction and alkylation. NP-HPLC profiles of the 2-AB labeled *N*-glycans released by PNGaseF from gel bands show that each peptide contains a different population of *N*-glycans (Reproduced by permission of The American Society for Biochemistry & Molecular Biology)

Both N- and O-linked glycans can be released by chemical means, for example, by base-catalyzed β-elimination (Carlson and Blackwell, 1968; Aminoff *et al*., 1980; Strecker *et al*., 1995) or hydrazinolysis (Fukuda *et al*., 1976; Strecker *et al*., 1981; Yamashita *et al*., 1984; Bendiak and Cumming, 1985; Patel *et al*., 1993). For the release of O-linked glycans, chemical release is the only effective method as no generic *O*-glycanases are currently known. The glycans released by β-elimination under the strong reducing conditions needed to prevent degradation (Aminoff *et al*., 1980), are converted to the alditol form, which is difficult to derivatize. This may not be a problem for analysis by mass spectrometry (MS) but it does preclude the use of high sensitivity–fluorescent detection. To preserve intact O- and N-linked glycans and a nonreducing terminal for derivatization, hydrazinolysis is preferred (Patel *et al*., 1993; Merry *et al*., 2002).

2.2. *Derivatization of glycans*

Released glycans are most commonly derivatized with a fluorophore to enable detection and quantitation in the sub-picomole range. Commonly used fluorophores include 2-aminopyridine (2-AP), 2-aminobenzamide (2-AB), 2-aminoanthranilic acid (2-AA), 2-aminoacridone (AMAC), and 8-aminonaphthalene-1,3,6-trisulfonic acid (ANTS) (see Anumula, 2000 and references therein). The choice of fluorescent label depends on the separation technology used. For example, a charged label is specifically required for capillary electrophoresis. Although underivatized glycans can be detected by mass spectrometry, derivatization may aid their ionization (Harvey, 1999; Harvey, 2000).

2.3. *Glycan sequencing*

The most commonly used high-resolution techniques for separating glycans for sequence analysis are high performance liquid chromatography (HPLC), capillary electrophoresis, and mass spectrometry.

Several different types of HPLC columns can be used to separate glycans: weak anion exchange (WAX), which separates glycans by charge (Tran *et al*., 2000; Royle *et al*., 2002) most commonly derived from sialic acid residues or sulfated sugars; reverse-phase (RP), which separates oligosaccharides on the basis of hydrophobic interactions (Kuraya and Hase, 1996; Guile *et al*., 1998; Royle *et al*., 2002); and normal-phase (NP), which separates glycans on amide columns (Takahashi *et al*., 1993; Guile *et al*., 1996) where retention time mainly depends on the first approximation of the size of the glycan (Guile *et al*., 1996; Guile *et al*., 1998; Royle *et al*., 2002). Normal-phase HPLC, which is used most widely, resolves neutral and charged glycans in a single run. By standardizing the retention time of each peak to that of an internal standard of hydrolyzed dextran as described by Guile *et al*. (1996), reproducible glucose unit (GU) values can be obtained for individual glycans. The incremental GU values are measures of the affinity of each glycan for the column matrix and are related to the hydrophilicity of each monosaccharide residue in the chain. The affinity also depends on how much of the hydrophilic surface is exposed to the column matrix. It is this feature that gives the fine specificity of the columns, allowing arm-specific isomers such as the biantennary mono galactosylated glycans, where the galactose may be on either the 3 arm (GU 6.48) or the 6 arm (GU 6.29), to be resolved. Preliminary structures are assigned from a database of GU values from known structures (e.g., the Oxford Glycobiology 2-AB Glycan Database) (Guile *et al*., 1996; Royle *et al*., 2002) and are confirmed by exoglycosidase digestions.

Glycans with similar compositions often coelute on NP-HPLC. To identify individual structures in complex mixtures more than one separation method may be required, for example, fraction collection from WAX-HPLC followed by normal-phase HPLC of the fractionated glycans (Guile *et al*., 1998; Royle *et al*., 2003). Figure 3 shows the profiles from mono- and disialylated glycans which coelute on NP-HPLC after separation by WAX-HPLC.

To determine the exact monosaccharide sequence and linkages, treatment with specific exoglycosidases, either individually or in arrays, followed by profiling of the digestion products by NP-HPLC, is often used (Hase *et al*., 1987; Tomiya *et al*., 1988; Anumula and Dhume, 1998). Changes in the positions of the peaks relative to the dextran standard (GU values) are related to both the type and the number of monosaccharides removed (Guile *et al*., 1996). Combinations of exoglycosidases can be used where they have sufficiently similar pH optima and buffer requirements and conditions may need to be optimized for complete removal of glycans from specific glycoproteins (Edge *et al*., 1992; Prime and Merry, 1998). In such cases, it may be necessary to check the specificity under the incubation conditions used, rather than those given by the supplier, as low levels of contaminating enzymes may be present. Figure 4 shows the NP-HPLC profiles of the *N*-glycans from secretory component of IgA following a series of exoglycosidase array digestions with the

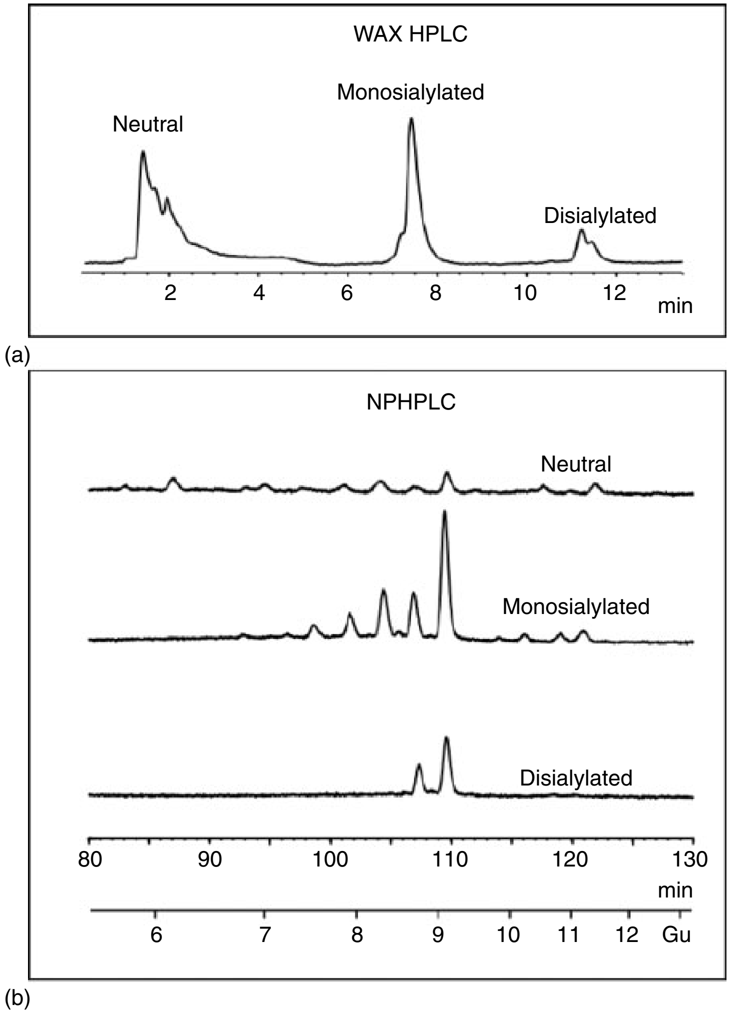

Figure 3 (a) shows the *N*-glycans from secretory component of human colostrum secretory IgA separated by weak anion exchange (WAX) HPLC. The differently charged fractions were collected and run on NP-HPLC (b). The data show that the two peaks that contain disialylated glycans elute with the same GU values as two monosialylated glycan structures (Reproduced by permission of The American Society for Biochemistry & Molecular Biology)

major structures annotated. In the top (undigested glycan pool) profile, both the two largest peaks contain a mixture of a di- and a monosialylated structures. The data from the WAX separation in Figure 3 was used to assign these structures.

The analysis of O-linked glycans is complicated by the presence of at least eight different core structures (*see* Article 65, **Structure/function of *O*-glycans**, Volume 6), compared with the trimannosyl-chitobiose core common to all N-linked glycans (Kornfeld and Kornfeld, 1985). This makes data interpretation more difficult than for the N-linked glycans.

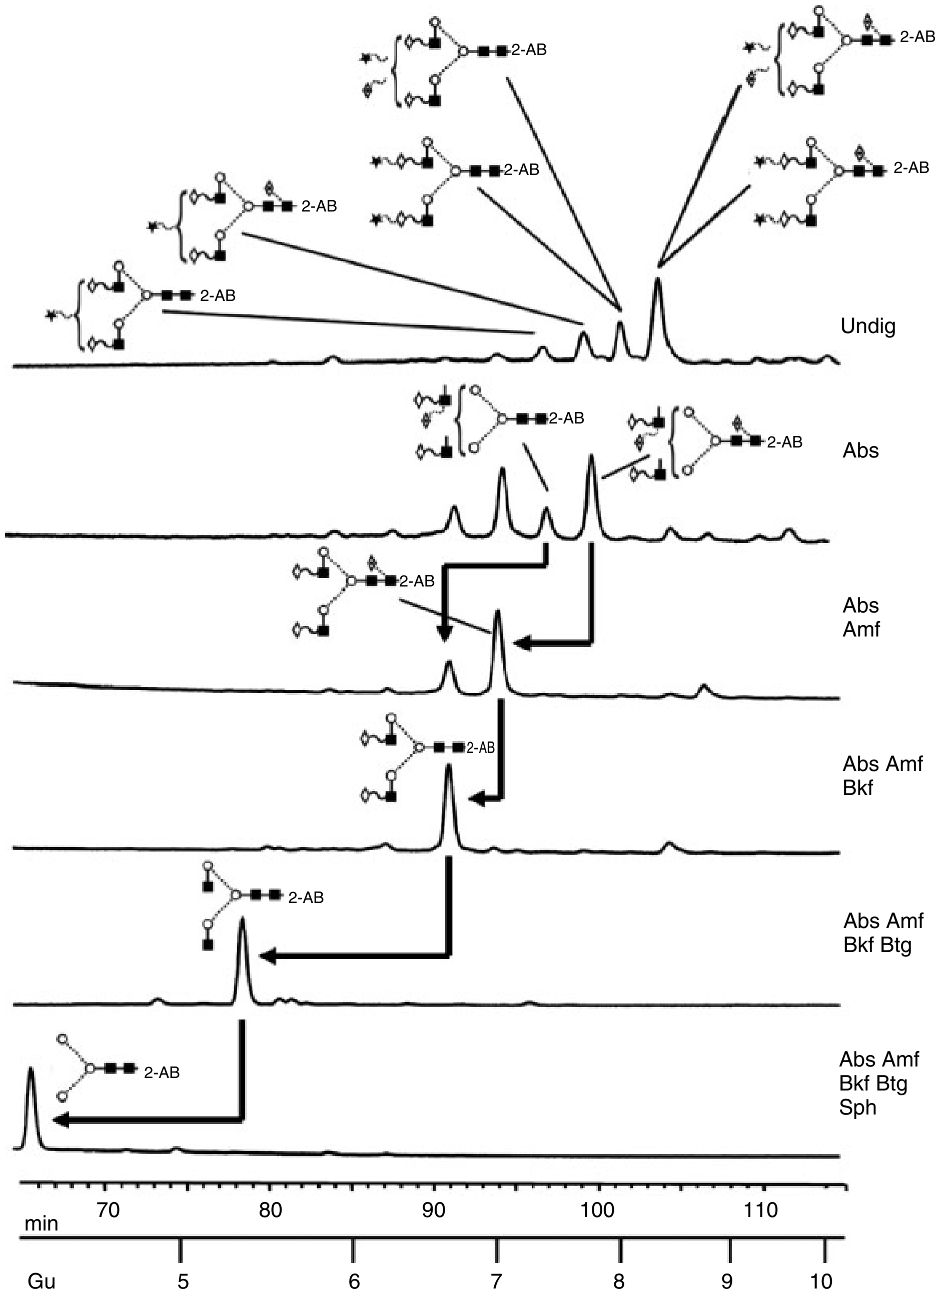

Figure 4 NP-HPLC profiles of 2-AB labeled *N*-glycans from secretory component of human colostrum secretory IgA. Aliquots of the total glycan pool were incubated with arrays of exoglycosidase enzymes then analyzed by NP-HPLC (undig = undigested). Exoglycosidase abbreviations: *Arthrobacter ureafaciens* sialidase (Abs); Bovine kidney α-fucosidase (Bkf); almond meal α-fucosidase (Amf); bovine testes β-galactosidase (Btg); *Streptococcus pneumoniae* β-*N*-acetylhexosaminidase (Sph). The major peaks are annotated using the scheme shown in Figure 6; arrows indicate movement of peaks following digestion

Recent advances in mass spectrometry instrumentation now allow profiling of a large number of different glycans (*see* Article 75, **Mass spectrometry**, Volume 6) but fragmentation or derivatization is required to give detailed information. Two main types of MS are currently used, namely, matrix assisted laser desorption ionization (MALDI) or electrospray (ESI-MS).

A combination of HPLC separation, mass detection, and fragmentation in LC-MS/MS with exoglycosidase digestion data can be used to sequence complicated N- and O-linked glycans (Mattu *et al*., 2000; Peracaula *et al*., 2003a,b; Royle *et al*., 2003). Figure 5 shows an example of MS fragmentation data for an *O*-glycan. If the glycoprotein comes from a source where the biosynthetic pathway is known, and where characteristic glycoproteins have already been sequenced, glycan sequences can be predicted from NP-HPLC data and confirmed with a limited number of enzymatic digestions.

Capillary electrophoresis (Camilleri *et al*., 1995) and high performance anion exchange chromatography (HPAEC) with pulsed amperometric detection (PAD) (Goodarzi and Turner, 1998) can also be used to analyze glycans. These techniques require careful standardization and optimization but can be used routinely for high-throughput screening (Goodarzi and Turner, 1998; Taverna *et al*., 1998). DNA sequencing instruments have also been modified for glycan profiling, particularly for the analysis of de-sialylated glycans (Callewaert *et al*., 2004).

2.4. *Presentation of data*

The established IUPAC nomenclature (1982) gives a complete and unambiguous description of each glycan but it is difficult to visualize the structures from the α-numeric code of the nomenclature, especially when comparing similar glycans. It is therefore common practice to use symbols that are more readily recognized by the human eye to depict the glycan structure, but there is no universal system in place, with different types of representation widely used. A format incorporating features from several existing schemes has been proposed (see Figure 6) that enables complex structural information to be displayed in simple cartoon format. Geometric symbols are used to represent individual monosaccharides, the shading of which has been chosen to represent derivatives of the native monosaccharide structure. For example, an open symbol means the sugar is not substituted, the filled symbol indicates that the monosaccharide contains an *N*-acetyl group, and a dot indicates a deoxy sugar. Hence, Gal is represented by an open diamond, GalNAc by a filled diamond, and deoxy-galactose (fucose) by an open diamond with a dot inside. The linkage positions are represented by the angle of the line linking adjacent monosaccharides (as first proposed by Kamerling and Vliegenthart, 1992) and most sugars are linked via the C1 reducing end (except sialic acids, which are linked via C2); this information is not represented in these diagrams. It is the position to which the reducing end of the sugar to the left attaches to the sugar on the right, which is represented by the bond angle. A continuous line indicates a β-linkage, a dotted line an α-linkage. Where the exact monosaccharide is unknown (e.g., from mass spec data), an appropriately shaded symbol is used; for example, an open hexagon for a hexose and a filled hexagon for a HexNAc. Unknown linkages are

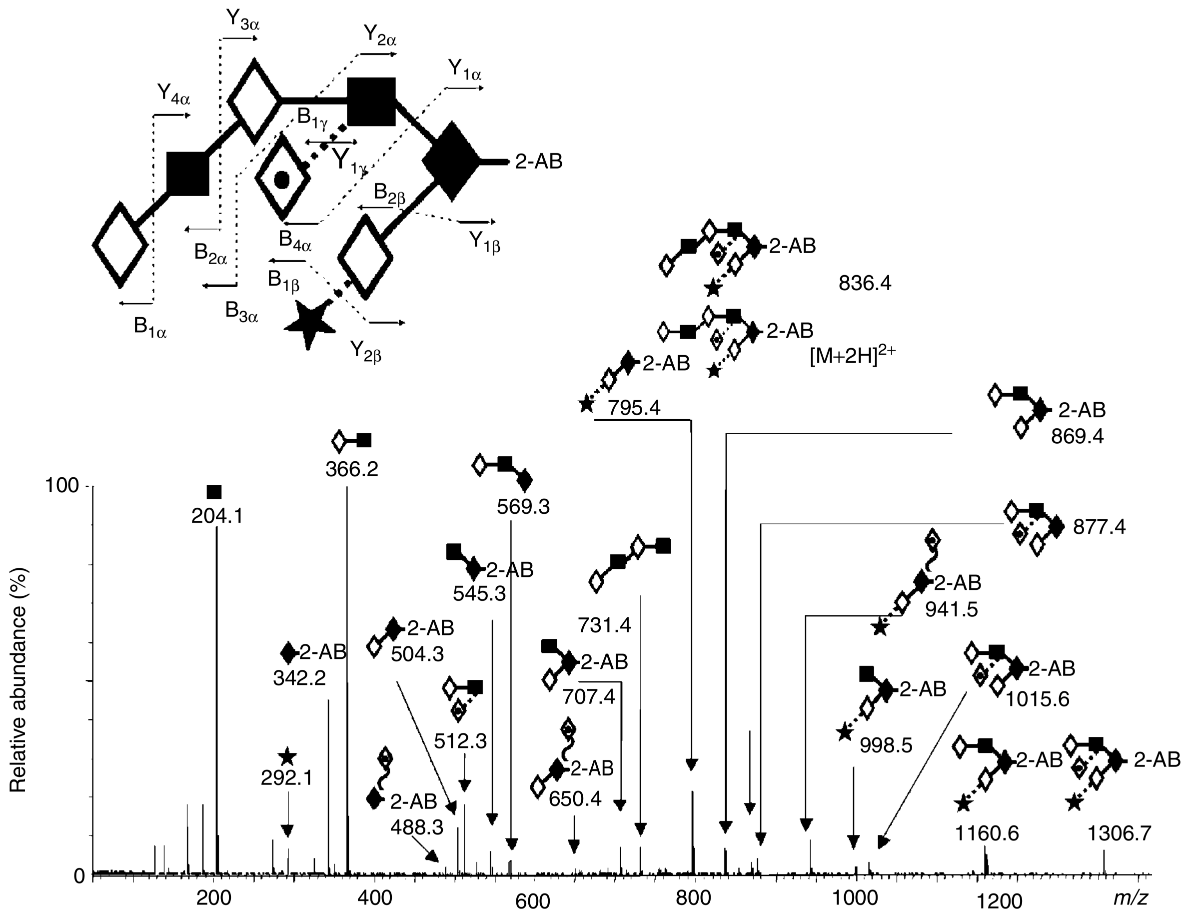

Figure 5 MS fragmentation of an *O*-glycan from secretory IgA by electrospray ionization following online NP-HPLC. The fragmentation scheme of the $[M+2H]^{2+}$ ion with *m/z* 836.4 is based on that of Domon and Costello (Domon and Costello, 1988) (Reprinted from Analytical Chemistry, **304**, Royle L. *et al*., pp 70–90, Copyright 2002, with permission from Elsevier)

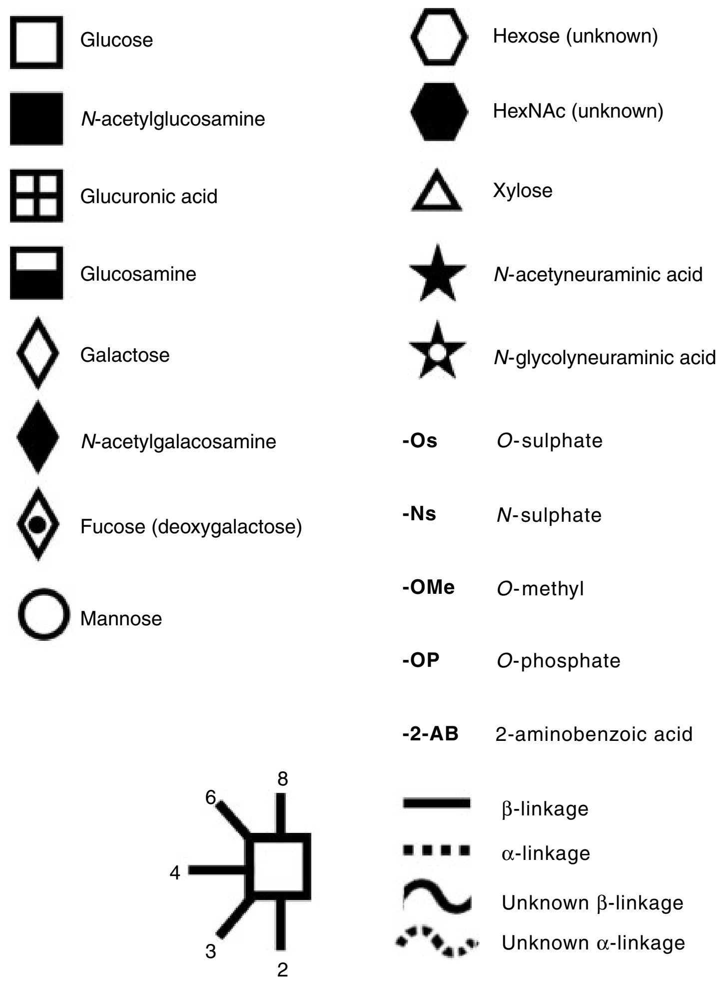

Figure 6 A scheme for the diagrammatic representation of glycans

represented by a wavy line. The normal D or L configuration or ring size (pyranose or furanose) that the monosaccharide adopts in glycans is assumed; for example, an open square represents D-glucopyranose. For fucose, the L configuration is taken as the default. Substituents such as sulfation or phosphorylation can also be shown by use of appropriate letters. This simple visual representation of both sugars and linkages clearly conveys the structural information needed when working with complex glycan structures.

Basic Techniques and Approaches

Glycosylphosphatidylinositol anchors – a structural perspective

Angela Mehlert
University of Dundee, Dundee, UK

1. Introduction

The fundamental role of glycosylphosphatidylinositol (GPI) anchors is to hold a protein onto the external surface of the plasma membrane of a cell, although many other functions have been suggested. A huge number of GPI-anchored proteins have been identified; they are a functionally diverse group and are ubiquitous in eukaryotic cells, particularly protozoa. There are also many instances in the protozoa where GPI structures are found on the parasites' cell surface but they are not attached to a protein (see McConville and Ferguson (1993), Branquinha *et al*. (1999), and Priest *et al*. (2003)).

2. Basic structure of GPIs

The first full structural characterization of a GPI, that of the variant surface glycoprotein (VSG) of *Trypanosoma brucei* and the result of about 6 years of work, was reported in 1988 (Ferguson *et al*., 1988), and the reason it took so long was the extraordinarily complex nature of the molecule. The GPI core is made up of three mannose residues linked to glucosamine that is joined to a *myo*-inositol residue. The inositol residue is part of a phosphatidylinositol (PI) or insitol-phosphoceramide (IPC) phospholipid that holds the protein next to the membrane. The signal peptide sequence required for a GPI to be attached to a protein consists of 15–20 hydrophobic residues followed by two small polar residues immediately before the GPI attachment site. An ethanolamine phosphate links the carboxy terminus of the protein to the third mannose residue of the GPI core. This basic structure may have various other groups attached, such as extra ethanolamine phosphate groups and carbohydrate side chains. Thus, the inherent complexity of GPIs, that include carbohydrate, lipid, phosphate, and peptide components, makes the structural analysis relatively difficult.

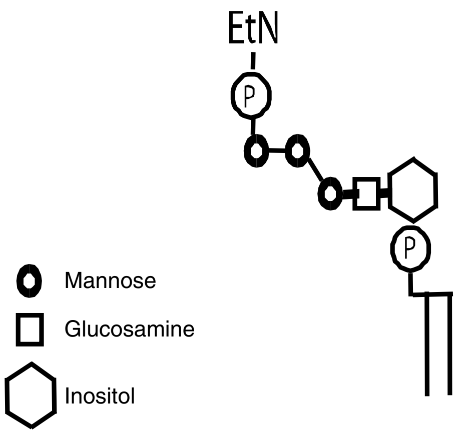

Figure 1 The core structure of a GPI anchor

3. Elucidation of the first GPI structures

The first anchors were characterized by basic structural chemistry techniques including ^{1}H NMR (nuclear magnetic resonance), gas chromatography-mass spectrometry (GC-MS) for composition and methylation linkage analysis, and specific enzymatic and chemical cleavages. The amount of protein needed for this characterization was substantial (over a hundred milligram of VSG was used) and although we now have access to much more sensitive instrumentation and specialized techniques, the availability of purified protein is still the main problem to be overcome in GPI analysis. However, with one exception, all protein-linked GPI anchors contain a core consisting of a minimum of three mannosyl residues in the following sequence:

EtN*P*-6Manαl-2Manαl-6Manαl-4GlcNαl-6(PI), see Figure 1, and this basic core is now relatively easy to confirm.

4. Procedures for GPI analysis

There are several chemical and enzymatic reagents that can be used for the selective cleavage of a GPI anchor structure. Some of these were originally used to help determine the early structures and are now applied to confirm the presence of a GPI anchor (Ferguson, 1993). They may also be used, in conjunction with chromatography or high performance thin layer chromatography (HPTLC), to obtain some structural information from native or [^{3}H]mannose-, [^{3}H]glucosamine-, [^{3}H]inositol-, or [^{3}H]fatty acid–radiolabeled GPI-anchored proteins or their GPI biosynthetic intermediates.

The most important analytical procedure is the nitrous acid deamination of the glucosamine residue of a GPI. This relatively gentle reaction (room temperature, pH 4.0) is highly selective for the glucosamine-inositol glycosidic bond because

it is dependent on the free amino group of the glucosamine residue. Apart from in GPIs, nonsubstituted glucosamines are uncommon in nature, the amino group usually being blocked by a sulfate or an acetate residue so there is little or no background. The deamination generates a free reducing terminus on the GPI glycan, a 2,5-anhydromannose. This reducing sugar can then be reduced to [1-^{3}H]2,5-anhydromannitol (AHM) by reduction with sodium borotritiide, thus introducing a radiolabel that aids further purification and analysis. Alternatively, the reducing terminus may be reductively aminated and attached to a fluorophore such as 2-amino-benzamide (2-AB). This technique may be easily performed using a 2-AB glycan labeling kit available commercially and has the advantage that it is simple to purify the fluorescently labeled glycans from the other products of the reaction by gel filtration or normal-phase HPLC. However, the cleanup of reduced and tritiated glycans requires removal of the substantial radiochemical contamination that is always present when using high specific activity $NaB^{3}H_4$. This cleanup procedure includes downward paper chromatography, followed by passage of the material through a mixed bed column in water (Ferguson, 1993).

5. Labeling of GPI anchors

When the GPI glycan is radioactively or fluorescently labeled and dephosphorylated with aqueous hydrogen fluoride (HF), it may be conveniently sequenced using exoglycosidases and HPTLC (Schneider and Ferguson, 1995). It is also possible to adapt the above protocol using only an aliquot of the glycan to label, the remaining material being reduced using $NaB^{2}H_4$. This allows a larger preparation to be handled while keeping the amount of radioactivity used at a reasonable level. The lipid moiety of the GPI is liberated by the nitrous acid reaction and this PI can be isolated by solvent extraction, purified on a micro silica column, and analyzed by negative ion tandem ES-MS (electrospray-mass spectrometry), as described by Thomson *et al*. (2002).

As mentioned earlier, the first anchors were characterized by NMR, which remains the only incontrovertible way to assign the anomericity of the glycosidic linkages. The easier option of specific cleavages achieved by either selective enzymatic or chemical techniques may be available for most of those linkages so far described, but if a negative result is obtained, or worse, a false-positive, mistakes can be made. However, obtaining the amount of material required for NMR analysis is not trivial. The use of a Shigemi tube and a cryoprobe can increase the sensitivity of the NMR up to tenfold, but the simplest structure to be solved would still require about 10 nmoles of purified material (personal observation). Also, there is no GPI NMR spectra reference database analogous to the one for N-linked oligosaccharides. However, if sufficient material and expertise is available, the first step in the analysis of a water soluble GPI would ideally be NMR in D_2O. NMR is a nondestructive technique, which means that further analysis may be done using the same sample, although it will probably contain contaminants that are present in even the best commercially available D_2O. Gel filtration in water will return the sample to a condition where it is suitable for further analysis.

6. Microscale analysis of GPIs

In reality, most analyses have to be done on a fraction of the material needed for NMR analysis and this has driven the search for other techniques. In the Ferguson lab in Dundee, progress has been made toward deriving a reliable microscale analysis regime, and methods are constantly being refined. Developments in mass spectrometry (MS) instrumentation and techniques have meant that although in the Fankhauser *et al*. paper (1993), the FAB (fast atom bombardment) MS of a permethylated GPI glycan could only be performed on 20 nmoles of material, but recently some proteomic-like analysis methods of GPI analysis have been published (Fontaine *et al*., 2003; Thomson *et al*., 2002; Priest *et al*., 2003). This approach is based on the use of partially purified proteins run on SDS-PAGE (sodium dodecyl sulphate-polyacrylamide gel electrophoresis), then Western blotted onto PVDF (polyvinylidene difluoride) membranes. These techniques overcome the problem of purifying large amounts of material and take advantage of the nonsubstituted glucosamine of GPIs that, as explained earlier, allows for specific labeling of the 2,5-AHM residue and release of the PI moiety. The ethanolamine phosphate connection, from the third mannose residue to the C-terminus of the protein, can then be exploited to release the labeled glycans from the protein and, therefore, from the PVDF membrane, by aqueous HF dephosphorylation. After digestion, the GPI will remain in the HF solution and the PVDF membrane can be removed. It appears that if there is enough protein for visualization by amido black on the membrane, it should be possible to deduce the basic structure of the molecule.

Unfortunately, using aqueous HF precludes the analysis of any other groups attached to the glycans through phosphate groups, for instance, other ethanolamine phosphate groups, will be lost. Also, the assumption has to be made that the ethanolamine phosphate bridge between the C-terminal of the protein and the GPI glycan is made to the third mannose, which has proved the case for all of the GPI structures solved so far.

Matrix assisted laser desorption ionization-time of flight (MALDI-TOF) analysis of sugars using various matrices can also be a useful technique. We have had most success with 2,5-dihydroxybenzoic acid as matrix, usually including trifluoroacetic acid in the solution to aid ionization. Glycolipids and mucin molecules may also be successfully analyzed by this technique (Almeida *et al*., 2000). Other cases where the amount of material has been limited have been resolved using permethylation of the neutral glycans prepared by HF digestion and then analyzed using positive ES-MS and ES-MS-CID (collision induced dissociation)-MS (Priest *et al*., 2003).

7. Proteomics type analysis of GPI

We have recently worked out a technique to help define whether a protein is GPI anchored by adapting the SDS-PAGE Western blotting technique, cutting out the band in question along with 2 control blank pieces of blot and a positive control (usually VSG). The PVDF membrane pieces are hydrolyzed in 6 M aqueous HCl

with a known amount of internal standard, as in our standard inositol analyses (Ferguson, 1993). The hydrolyzed material is dried and derivatized with tri-methylsilyl reagent, then analyzed by GC-MS using a SIM (selective ion monitoring) method, which scans for the ions characteristic of inositols (m/z 305 and 318). This method is very destructive on the GC column and the MS ion source will become contaminated from the acid hydrolysis of the PVDF membrane; however, it has proved useful in some cases where the amount of material available precluded the use of other techniques.

Introductory Review

Classification of proteins into families

Nicola J. Mulder and Rolf Apweiler
European Bioinformatics Institute, Cambridge, UK

1. Introduction

In order to provide a review on the classification of proteins into families, it is necessary to describe what a protein family is and why and how they should be classified into families. A protein family has a number of different definitions, but the basic concept agreed upon is that it is a group of evolutionarily related proteins. The Dictionary of Cell and Molecular Biology (Lackie and Dow, 1999) **http://www.mblab.gla.ac.uk/∼julian/Dict.html**) describes a gene family as: "a set of genes coding for diverse proteins which, by virtue of their high degree of sequence similarity, are believed to have evolved from a single ancestral gene". Therefore, the basis for classifying proteins into families is their sequence similarity. A protein may be related to another very specifically at the subfamily level, it can be related to more diverse proteins at a family level, and it is then related to even more diverse proteins at the superfamily level. The number of common properties of the proteins at each level increases toward the subfamily level.

Why the interest in protein classification into families? Genome sequences of a large range of different organisms are flooding into the public databases. The sequence data is largely entering the databases unannotated and requiring further analysis to functionally characterize the proteins. DNA and protein sequences have traditionally been analyzed by comparing new sequences to existing ones of known function. This is all very well if the existing ones have a known function, but the flood of new sequences has resulted in an increased proportion of unknown to known sequences in the databases. Therefore, new sequences have a high likelihood of not receiving annotation from a sequence similarity search. It thus follows that the more characterized sequences in the database, the more efficiently new sequences will be functionally annotated. This presents a chicken and egg situation – where to start in the circle! However, as mentioned previously, protein sequences may be classified on different family levels in which certain functional characteristics are conserved. The possibility of classifying proteins into families thus presents an opportunity for inference of a conserved function on all members of the family and thus increasing the pool of characterized proteins in the database.

There are two main methods for classification of proteins into families: sequence clustering and protein signatures. Methods of clustering related protein sequences

by their similarities are well established and quick, but have their drawbacks. An important factor is the low probability of detecting distant relationships between new and existing sequences of the same protein family. Bioinformatics has evolved rapidly since its initiation, which has led to the development of new tools to solve these problems. A number of scientists in this discipline have independently developed the concept of protein signatures as a means to protein functional annotation by exploiting known similarities between related protein sequences and using mathematics to describe them. A signature is a "description" of an entity and it defines the characteristics associated only with that entity. Sequence clustering and protein signatures will be discussed in detail in this chapter.

2. Sequence clustering

Sequence clustering methods are generally entirely automated, and make the assumption that members of a protein family will cluster together on the basis of sequence similarity. An example of a database that uses this method is ProDom (Corpet *et al*., 2000). The general philosophy of ProDom construction is that autonomously evolving protein domains can be recognized as shuffled in present day sequences by sequence comparison methods. It takes all proteins in UniProt (the successor of Swiss-Prot, TrEMBL (Boeckmann *et al*., 2003), and PIR) (Apweiler *et al*., 2004), removes fragments, identifies the smallest remaining sequence, and uses this as a query sequence to search the protein database using PSI-BLAST (Altschul *et al*., 1997). The sequences that hit are made into a new ProDom domain family and removed from the protein database. The remaining sequences are once again sorted by size, and the process is repeated until completion. In this way, ProDom groups all the nonfragment sequences in Swiss-Prot and TrEMBL into more than 150 000 families. Another major alignment database is PIR-ALN (Srinivasarao *et al*., 1999), a database of annotated protein sequence alignments derived automatically from the PIR sequence database, with alignments at the superfamily and domain level. Other widely used cluster databases are ProtoMap (Yona *et al*., 2000), Systers (Krause *et al*., 2000), and CluSTr (Kriventseva *et al*., 2003). All these databases offer an automatic classification of all UniProt proteins into groups of related proteins on the basis of pairwise similarities. For more details on sequence clustering, *see* Article 92, **Classification of proteins by clustering techniques**, Volume 6.

3. Protein signatures and databases

There is a certain amount of inherent information in a protein sequence, but from one sequence it is difficult to discover what this information describes. However, if a number of related sequences are aligned, conserved regions can be identified, which may be an indication of function. These conserved areas of a protein family, domain, or functional site can be used to develop a description of the family using several different methods, including regular expressions (for patterns of conserved residues), profiles, and hidden Markov models (HMMs). The

Article 91, **Classification of proteins by sequence signatures**, Volume 6 gives a thorough introduction into the different methods used by the major protein signature databases available to the public.

4. Regular expressions

Regular expressions (or patterns) describe a group of amino acids that constitute a usually short, characteristic motif within a protein sequence. These motifs arise because these region(s) of a protein are important for activity.

PROSITE (Hulo *et al*., 2004) is a database that uses such patterns. These are built from sequence alignments of related sequences, which are taken from either a well-characterized protein family derived from the literature or from the result of sequence searches against Swiss-Prot and TrEMBL. The alignments are scanned for conserved regions involved in the catalytic activity or substrate binding. Patterns derived from these regions specify which amino acid(s) may or may not occur at each position. The syntax of a PROSITE pattern can be illustrated by the following hypothetical pattern: <M-G-x(3)-[IV]2-x-{FWY}, which is restricted at the N-terminus of a sequence (<) and translated as Met- Gly-any residue-any residue-any residue-[Ile or Val]-[Ile or Val]-any residue-{any residue but Phe or Trp or Tyr}. Patterns have many advantages, but they also have their limitations across whole sequences and for more divergent proteins.

5. Profiles

A profile is a table of position-specific amino acid weights and gap costs. The table describes the probability of finding a particular amino acid at a given position in the sequence (Gribskov *et al*., 1990). The numbers in the table (scores) are used to calculate similarity scores between a profile and a sequence for a given alignment. For each set of sequences, a threshold score is calculated to differentiate between true and nontrue matches to the profile.

PROSITE creates profiles for their database to complement the patterns (Bucher *et al*., 1996). For these, they also start with multiple sequence alignments, and use a symbol comparison table to convert residue frequency distributions into weights, resulting in a table of position-specific weights (Gribskov *et al*., 1990). A similarity score is calculated between the profile and sequences in Swiss-Prot, and the profile is refined until only the intended set of protein sequences scores above the threshold score for the profile. For a detailed description of PROSITE, *see* Article 84, **Functionally and structurally relevant residues in PROSITE motif descriptors**, Volume 6.

PRINTS (Attwood *et al*., 2003) uses the concept of profiles in a different way to develop their database of "fingerprints". A fingerprint is a group of conserved motifs used to characterize a protein family. Instead of focusing on small conserved areas only, the occurrence of these conserved areas across the whole sequence is taken into account. Profiles are built from a multiple sequence alignment for small conserved regions in the sequence, and together make up a fingerprint.

During creation of the fingerprints, each motif is used to scan the protein sequence database and the hit lists are correlated to add sequences to the original alignment. New motifs are then generated and the process is repeated until convergence. Recognition of individual elements in the fingerprint is mutually conditional, and true members match all elements in order while members of a subfamily may match part of the fingerprint. Many fingerprints have been created to identify proteins at the superfamily as well as the family and subfamily levels. For this reason, many of the fingerprints are related to each other in an ordered hierarchical structure. *See* Article 85, **The PRINTS protein fingerprint database: functional and evolutionary applications**, Volume 6 for a detailed description of the PRINTS database.

6. Hidden Markov models

HMMs (Krogh *et al*., 1994) are statistical models that are based on probabilities rather than on scores. The HMMER package, written by Sean Eddy (**http://hmmer.wustl.edu/**), is based on Bayesian statistical models and is the major implementation of HMMs. It allows users to create an HMM from a sequence alignment and to search a database of sequences against the HMM. Many databases, for example, Pfam (Bateman *et al*, 2004), SMART (Letunic *et al*., 2004), TIGRFAMs (Haft *et al*., 2003), PIR SuperFamily (Wu *et al*., 2004), and SUPERFAMILY (Madera *et al*., 2004) use HMMs implemented in their own interpretations.

Pfam (Bateman *et al*., 2004) is a large collection of protein families available via the web and in flat file format. There are two sections in the Pfam database, PfamA, which is a set of high-quality manually annotated models, and PfamB, which has higher coverage, but is fully automated with no manual intervention. PfamA entries initiate from a seed alignment of the protein sequence region covered by the family or domain, which is trimmed manually to ensure accurate domain boundaries. A full alignment and an HMM are then created from the final alignment and annotation is added. PfamB is created from automatic clustering of the protein sequences in Swiss-Prot and TrEMBL by ProDom with PfamA members removed. Pfam has a high coverage of sequence space and is used extensively for the annotation of genomes. The chapter Article 86, **Pfam: the protein families database**, Volume 6 gives an in-depth description of Pfam.

SMART (a Simple Modular Architecture Research Tool: Letunic *et al*., 2004) is a database that develops HMMs to facilitate the identification and annotation of genetically mobile domains and the analysis of domain architectures. These are built from hand-curated multiple sequence alignments of representative family members based on tertiary structures where possible, otherwise those found by PSI-BLAST (Altschul *et al*., 1997). The models created are used to search the database for additional members to be included in the sequence alignment. This iterative process is repeated until no further homologs are detected. SMART focuses on models for domains found in signaling, extracellular, and chromatin-associated proteins, and provides useful tools for the analysis of protein domain composition.

TIGRFAMs (Haft *et al*., 2003) are a collection of protein families created to assist in sequence annotation, particularly from microbial genomes. The focus is

on HMMs that group homologous proteins conserved with respect to function. The models are produced in a similar way to those in Pfam and SMART, but should only hit equivalogs, that is, proteins that have been shown to have the same function. However, where the biology of a protein family does not support the construction of equivalog models, superfamily HMMs are developed and a hierarchy may exist. TIGRFAMs are a useful complement to Pfam where the latter may only have generalized models for a protein family not necessarily restricted to functional equivalents. A detailed description of TIGRFAMs is available in the chapter Article 88, **Equivalog protein families in the TIGRFAMs database**, Volume 6.

PIR SuperFamily (Wu *et al*., 2004), known as *PIRSF*, is a protein classification system based on evolutionary relationships between whole proteins. Preliminary PIRSF clusters are computationally defined using both pairwise-based and cluster-based parameters. In each cluster, proteins sharing the same domain composition and similar lengths are manually identified and grouped as curated families. HMMs are created from these families to populate the PIRSF database. A new sequence must be matched by the HMM and satisfy the length restriction to be a member of a family. The focus on classification of whole proteins, not individual domains, allows annotation of specific biological functions of proteins as well as of generic biochemical functions. PIRSF is described in more detail in the chapter Article 87, **The PIR SuperFamily (PIRSF) classification system**, Volume 6.

SUPERFAMILY (Madera *et al*., 2004) is a database of HMMs based on protein structure rather than sequence. The HMMs in the database represent all proteins of known structure, and are based on the SCOP (Andreeva *et al*., 2004) classification of proteins. Each model corresponds to a SCOP domain, and aims at representing an entire superfamily. Many Pfam domains are also based on SCOP domains; however, structural families often differ from sequence-based ones since similar sequences may have similar structures, but the reverse is not always true. SUPERFAMILY has been applied to whole genomes and is used for genome comparisons and analysis of the distribution of structural families in the genomes.

7. Integration of the databases

Each of the methods for protein family classification has their advantages and disadvantages. Patterns are easy to generate and useful for small conserved regions like active sites or binding sites, but fail to provide information about the rest of the sequence, and may reject significant family members. Profiles and HMMs are efficient at identifying divergent members, but HMMs, in particular, are slow to develop and use. PRINTS fingerprints are strong in detecting families on different levels, but are weak in domains and sites. The ideal protein classification system would use all of the databases together.

Many of them already have interactions and exchange of data between them. For example, some use ProDom families as a starting point for their signatures, and many cross-reference each other where applicable. The obvious solution has recently been provided by several groups, which have made an effort to integrate some or all of these databases into a single coherent protein signature resource.

The integrated database resources include MetaFam (Silverstein *et al*., 2001), CDD (Wheeler *et al*., 2001) and InterPro (Mulder *et al*., 2003). MetaFam automatically create supersets of overlapping families from Blocks+, DOMO, Pfam, PIR-ALN, PRINTS, Prosite, ProDom, and SBASE (Murvai *et al*., 2001) using set theory to compare these databases. They provide reference domains covering the total area. CDD is a database of domains derived from SMART, Pfam, and contributions from NCBI LOAD (Library Of Ancient Domains). These integrated resources all use automatic methods, and in some cases simply provide the capability to search the individual databases from one page. InterPro, on the other hand, is produced by the members of the individual protein signature databases, and the integration process is manual. In the database, the similarities and differences between the contributing member database signatures are rationalized, so a user is clear on how to fathom multiple hits to a protein sequence. This makes InterPro a powerful resource that is greater than the sum of the individual components of which it is comprised. InterPro is discussed in detail in the chapter Article 83, **InterPro**, Volume 6.

8. Discussion

The classification of proteins into families is the first step in the process of functionally annotating unknown proteins in the database. The methods and databases described in this chapter are crucial to this process, and although they have developed independently they have involuntarily converged to provide a formidable and reliable combination for use in the automatic annotation of protein sequences. InterPro unites them to exploit their strengths and compensate for potential weaknesses and provides the bench scientists and genome sequencing centers with a gateway for analyzing their sequences of interest.

InterPro entries, through the protein signatures that describe them, group proteins into families or those with common domains. Once protein sequences are classified into families, if one or more members are well characterized, it is possible to make assumptions about the function of all the other members. Having a defined method for grouping the proteins means that new protein sequences entering the database can automatically be assigned to their relevant protein families without having to recreate the methods themselves. The result is a powerful tool for classifying and characterizing proteins that is scalable for application to whole genomes of many diverse organisms. As new protein families emerge, methods for classifying them can be developed until nearly all protein families in biological space are represented. It is important to note, however, that protein classification methods provide useful and often very accurate predictions of protein function, but these should ultimately be verified by experimental evidence.

Specialist Review

Metalloproteins

Kirill Degtyarenko
European Bioinformatics Institute, Cambridge, UK

1. Introduction

Metalloproteins are an immensely diverse class of biological coordination compounds. The most important biochemical processes, including respiration, oxygenic photosynthesis, regulation of transcription and translation, nitrogen fixation, and metabolism of xenobiotics, depend on metalloproteins. Metalloenzymes were the first biological catalysts on Earth. About one-third of all structurally characterized proteins contain metals, while over 50% of all proteins are estimated to be metalloproteins.

From the first studies on hemoglobin onward, spectroscopic and other physical methods have played a crucial role in research into metalloproteins. Many of them possess distinctive colors, which explains why metalloproteins attracted attention early in the history of biochemistry. Indeed, polypeptides absorb light mostly in the ultraviolet region, and the colors of proteins are due to nonpeptide chromophores. The specific absorption maxima (in nanometers) were historically used in the names of chromophores and/or proteins, as in cytochrome b_{562}, cytochrome c_{554}, cytochrome P450, coenzyme F430, P680, and P700 centers of photosystems and so on, while other metalloproteins were given such colorful names as “azurin” and “purple acid phosphatase” (in this latter example, purple is the color of the enzyme, not of the acid). Incidentally, metalloenzyme urease was the first enzyme ever to be crystallized; later, myoglobin became the first protein to have a known three-dimensional (3D) atomic structure. Table 1 puts some major landmarks in the history of physics and chemistry into the context of metalloprotein science.

Many aspects of metalloprotein structure and function remain obscure. One of these concerns metal selectivity. It is not clear why some proteins display an almost absolute preference for one metal over another, for example, in tungsten and molybdenum enzymes (L’vov *et al*., 2002), while others easily incorporate “nonnative” metals. In the metalloprotein world, sequence homology does not guarantee similarity, at least at the level of the active centers. It is not surprising then that the traditional bioinformatics “approach” is to view metals as an irritating complication best to avoid.

Paradoxically, apparently complicated metalloproteins may hold the key to the solution of one of the most challenging problems of computational biology: the protein-folding problem. It is known that metal ions play a crucial role in proteinfolding and stabilization. Moreover, the evidence grows that successful

Table 1 Landmarks in the history of metalloproteins

Year		Nobel prize
1862	Ernst Felix Hoppe-Seyler (1825–1895) observes the absorption spectrum of hemoglobin.	
1864	Hoppe-Seyler names and crystallizes hemoglobin.	
1879	Hoppe-Seyler proposes that chemical structures of hemin and chlorophyll are similar.	
1886	Charles Alexander MacMunn (1852–1911) suggests that tissues contain heme pigments other than hemoglobin.	
1892	Alfred Werner (1866–1919) develops the coordination theory of inorganic compounds.	Chemistry 1913
1894	Gabriel Bertrand (1867–1962) describes laccase.	
1895	Wilhelm Conrad Röntgen (1845–1923) discovers X-radiation.	Physics 1901
1895	Gabriel Bertrand describes tyrosinase.	
1903	Mikhail Tswett (1872–1919) separates the plant pigments including chlorophylls with the help of his new method that he calls "chromatography".	
1912	Max von Laue (1879–1960) discovers the diffraction of X rays by crystals.	Physics 1914
1912	William Henry Bragg (1862–1942) develops the X-ray spectrometer; his son, William Lawrence Bragg (1890–1971), discovers the law of X-ray diffraction (the Bragg law).	
1913	W.H. Bragg and W.L. Bragg solve the first crystal structure: sodium chloride.	Physics 1915
1913	Richard Martin Willstätter (1872–1942) determines the chemical structure of chlorophyll.	Chemistry 1915
1924	Otto Heinrich Warburg (1883–1970) describes the *Atmungsferment* (cytochrome *c* oxidase).	Medicine 1931
1925	David Keilin (1887–1963) names cytochromes.	
1927	The Svedberg (1884–1971) measures the molecular weight of hemoglobin by ultracentrifugation.	Chemistry 1926
1926	James Batcheller Sumner (1887–1955) obtains the first crystalline enzyme, urease.	Chemistry 1946
1928	Chandrasekhara Venkata Raman (1888–1970) discovers the light scattering effect called after him.	Physics 1930
1929	Hans Fischer (1881–1945) synthesizes hemin.	Chemistry 1930
1939	Axel Hugo Theodor Theorell (1903–1982) purifies cytochrome *c*.	Medicine 1955
1941	Theorell crystallizes horseradish peroxidase.	
1944	Evgeny Zavoisky (1907–1976) discovers electron paramagnetic resonance (EPR).	
1945	Independent discovery of nuclear magnetic resonance (NMR) by Felix Bloch (1905–1983) and Edward Mills Purcell (1912–1997).	Physics 1952
1955	Osamu Hayaishi and Howard S. Mason independently discover biological oxygenation.	
1956	Rudolph A. Marcus (b. 1923) publishes the first paper in his series "On the Theory of Oxidation-Reduction Reactions Involving Electron Transfer".	Chemistry 1992
1956	George Feher (b. 1924) develops the ENDOR (Electron Nuclear Double Resonance) method.	
1957	Dorothy Crowfoot Hodgkin (1910–1994) determines the X-ray structure of vitamin B_{12}.	Chemistry 1964
1957	Jens Christian Skou (b. 1918) discovers the ion-transporting enzyme Na^+, K^+-ATPase.	Chemistry 1997
1957	Rudolf Ludwig Mössbauer (b. 1929) discovers recoil-free γ-ray resonance absorption (Mössbauer effect).	Physics 1961
1960	John Cowdery Kendrew (1917–1997) reports the first three-dimensional atomic structure of a protein, myoglobin; Max Ferdinand Perutz (1914–2002) reports the X-ray structure of hemoglobin.	Chemistry 1962
1962	Leonard E. Mortenson discovers ferredoxin in *Clostridium pasteurianum*.	
1962	Ryo Sato (1923–1996) and Tsuneo Omura (b. 1930) identify P450 as a hemoprotein.	

Table 1 (*continued*)

Year		Nobel prize
1967	W.M. Fitch and E. Margoliash calculate the phylogenetic tree by comparing amino acid sequences of cytochromes *c*.	
1968	Kurt Wüthrich (b. 1938) publishes the high-resolution proton magnetic resonance spectra of myoglobin.	Chemistry 2002
1969	Joe McCord and Irvin Fridovich suggest that the function of "hemocuprein" is the catalysis of the reaction: $O_2^{\bullet-} + O_2^{\bullet-} + 2H^+ \rightarrow O_2 + H_2O_2$ and coin the term "superoxide dismutase".	
1972	Thomas Spiro obtains the resonance Raman spectra of myoglobin and cytochrome *c*.	
1976	Shuji Katsuki, William Arnold and Ferid Murad (b. 1936) discover the biological effect of nitric oxide (NO): activation of guanylate cyclase.	Medicine 1998 (Murad)
1977	Wüthrich and Richard R. Ernst (b. 1933) publish the first 2D ^{1}H NMR spectrum of a protein.	Chemistry 1991 (Ernst)
1978	Hans Freeman and colleagues determine the X-ray structure of poplar plastocyanin.	
1984	Johann Deisenhofer (b. 1943), Robert Huber (b. 1937) and Hartmut Michel (b. 1948) solve the first X-ray structure of a membrane protein, the photosynthetic reaction center.	Chemistry 1988
1987	Salvador Moncada (b. 1944) and Louis J. Ignarro (b. 1941) independently prove the suggestion of Robert F. Furchgott (b. 1916) that the "endothelium-derived relaxing factor" is identical to NO.	Medicine 1998 (Furchgott, Ignarro)
1993	Norbert Krauß and coauthors solve the X-ray structure of photosystem I at 6 Å.	
1995	Simultaneously, the X-ray structures of cytochrome *c* oxidase are published by So Iwata (enzyme from *Paracoccus denitrificans*) and Tomitake Tsukihara (bovine heart enzyme).	
2003	The structures of cytochrome b_6f complex are solved in the teams of Jean-Luc Popot (*Chlamydomonas reinhardtii*) and William A. Cramer (*Mastigocladus laminosus*).	

folding of many metalloproteins only occurs in the presence of specialized metal carrier proteins called metallochaperones. Therefore, the elucidation of the real chemical and biological environment of protein folding is required if we want to get closer to this Holy Grail of computational biology.

Throughout the text, cross-references to biological databases such as UniProt (Apweiler *et al*., 2004), EMBL (Kulikova *et al*., 2004), InterPro (*see* Article 83, **InterPro**, Volume 6), and PDB (*see* Article 71, **The Protein Data Bank (PDB) and the Worldwide PDB http://www.wwpdb.org**, Volume 7) are used in the form (Database:Accession Number). The referenced database entries themselves contain comprehensive literature and database references. Additional Worldwide Web resources relevant to this chapter are compiled in Table 6.

2. Functional classification of metal centers in proteins

Metal centers in proteins can be classified according to their function:

- "permanent" centers
  - catalytic

  - electron transfer
  - exciton transfer
  - gas sensing
  - gas storage
- structural
  - "transient" centers
  - metal sensing
  - metal storage and transport.

It is a matter of taste whether proteins with "transient" metal centers qualify to be called metalloproteins. The distinction is not as rigid as it sounds: some metal centers can switch their roles. The iron-responsive element binding protein (IRE-BP) functions either as an active aconitase (aconitate hydratase; EC 4.2.1.3), when cells are iron-replete, or as an active mRNA-binding protein, when cells are iron-depleted (Rouault and Klausner, 1996). Many metalloproteins have more than one functional metal center.

There are four classes of functional groups collectively referred to as polypeptide-derived, or *endogenous*, ligands:

- side chain groups: amide (Asn, Gln), amino (Lys), carboxyl (Asp, Glu), guanidino (Arg), hydroxyl (Ser, Thr), imidazole (His), phenol (Tyr), selenol (Sec), sulfide (Met), and thiol (Cys)
- carbonyl and amide of the main chain
- amino group at the N-terminus
- carboxylate group at the C-terminus.

Some posttranslational modifications add to this list; for instance, the carboxyl group of N^6-carboxy-L-lysine provides a bridging ligand for the two Ni atoms in the urease active center.

Ligands not derived from a polypeptide are called *exogenous* (Holm *et al*., 1996). Exogenous ligands range from simple inorganic entities (e.g., oxide, hydroxide, sulfide, water and other solvent-derived molecules, or such physiological ligands as dioxygen or nitric oxide) to polydentate organic compounds, for example, porphyrins or corrins.

3. Metal centers in metalloproteins

3.1. Mononuclear centers

The simplest metal center consists of one metal atom and its first coordination shell ligands. The functional roles of mononuclear centers are diverse: catalytic (Fe in lipoxygenase, InterPro:IPR000907), electron-transfer (Cu in blue copper proteins, InterPro:IPR001235), metal transport (Ni in urease metallochaperone UreE, UniProt:P18317), metal sensing (copper efflux regulator CueR, PDB:1Q05), and structural (various Ca and Zn centers). This is reflected in the diversity of

their coordination geometries, with coordination numbers varying between 2 and 8. Vanadium haloperoxidases (InterPro:IPR008934) have an unusual mononuclear center, vanadate (VO_4^{3-}) (Figure 1a).

3.2. Dinuclear centers

Dinuclear (binuclear) centers contain two or more metal atoms within a single coordination shell. Both homodinuclear (dicobalt, dicopper, diiron, dimanganese, dimagnesium, dinickel, dizinc) and heterodinuclear (copper,zinc; iron,manganese; iron,nickel; iron,zinc) centers have been described. In dinuclear centers, two metal atoms can be linked by one or more bridging ligands. The dinuclear centers participate in catalysis (Cu–Zn in Cu,Zn superoxide dismutase; Ni–Ni in urease), electron-transfer (Fe_2S_2 in ferredoxins), oxygen storage (Cu–Cu in hemocyanins), and H_2 sensing (Ni–Fe in regulatory hydrogenase) (Haumann *et al*., 2003).

3.3. Polynuclear centers

Polynuclear centers contain more than two metal atoms within a single coordination shell. The functional roles of polynuclear centers include structural (iron–sulfur cluster loop domain, InterPro:IPR003651), electron transfer (Fe_3S_4 and Fe_4S_4 clusters in bacterial-type ferredoxins), catalysis (nitrogenase iron–molybdenum cofactor; Mn_4 cluster in the oxygen-evolving complex of the photosystem II) and oxygen sensing (Fe_4S_4 cluster in FNR regulator; UniProt:P03019).

3.4. Metal–organic molecule complex centers

Many metalloproteins employ organic molecules as polydentate exogenous ligands. The metals in these centers could have as little as one or even no endogenous ligands.

Naturally occurring tetrapyrroles form tight complexes with metal ions, such as Co (vitamin B_{12}), Fe (hemes), Mg (chlorophylls), and Ni (coenzyme F430). The coordination geometries of metals in tetrapyrrole complexes are square planar, square pyramidal, or octahedral.

Molybdenum and tungsten enzymes have a pterin cofactor that coordinates to the metal atom via its dithiolene group. The pterin cofactor common to Mo- and W-containing enzymes is frequently referred to by the trivial name *molybdopterin*, but this term refers to the metal-free organic cofactor alone. Fischer *et al*. (1998) suggested a systematic nomenclature for these cofactors and their metal-free pterin units. The cofactor is considered to be a derivative of ene-dithiol pyranopterin (H_2Dtpp). In eukaryotic enzymes, the terminal phosphate group is attached to the cofactor via the methylene group (R = mP), whereas in enzymes from prokaryota it can be linked to a nucleotide of adenine, cytosine, guanine, or inosine (R = mADP, mCDP, mGDP, or mIDP). Thus, the molybdenum cofactor of the aldehyde

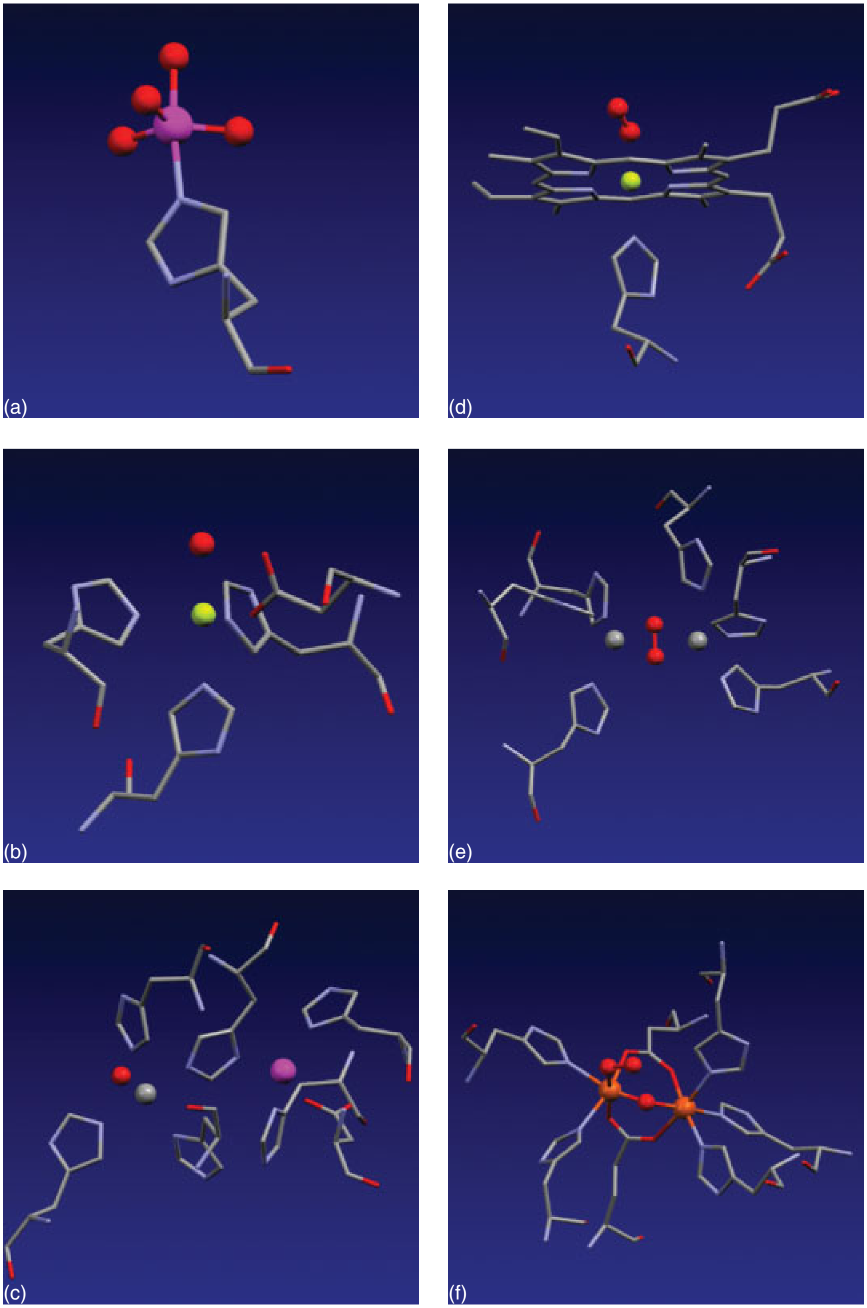

Figure 1 Examples of metal centers in proteins. (a) Mononuclear vanadate center in vanadium-containing chloroperoxidase from *Curvularia inaequalis* (PDB:1IDQ). (b) Mononuclear iron center in cambialistic superoxide dismutase from *Propionibacterium shermanii* (PDB:1AR5). (c) Dinuclear copper–zinc center in superoxide dismutase from *Xenopus laevis* (PDB:1XSO). (d) Heme *b* in sperm whale oxymyoglobin (PDB:1A6M). (e) Dinuclear iron center in oxyhemerythrin from *Themiste dyscrita* (PDB:1HMO). (f) Dinuclear copper center in oxyhemocyanin from *Octopus dofleini* (PDB:1JS8).

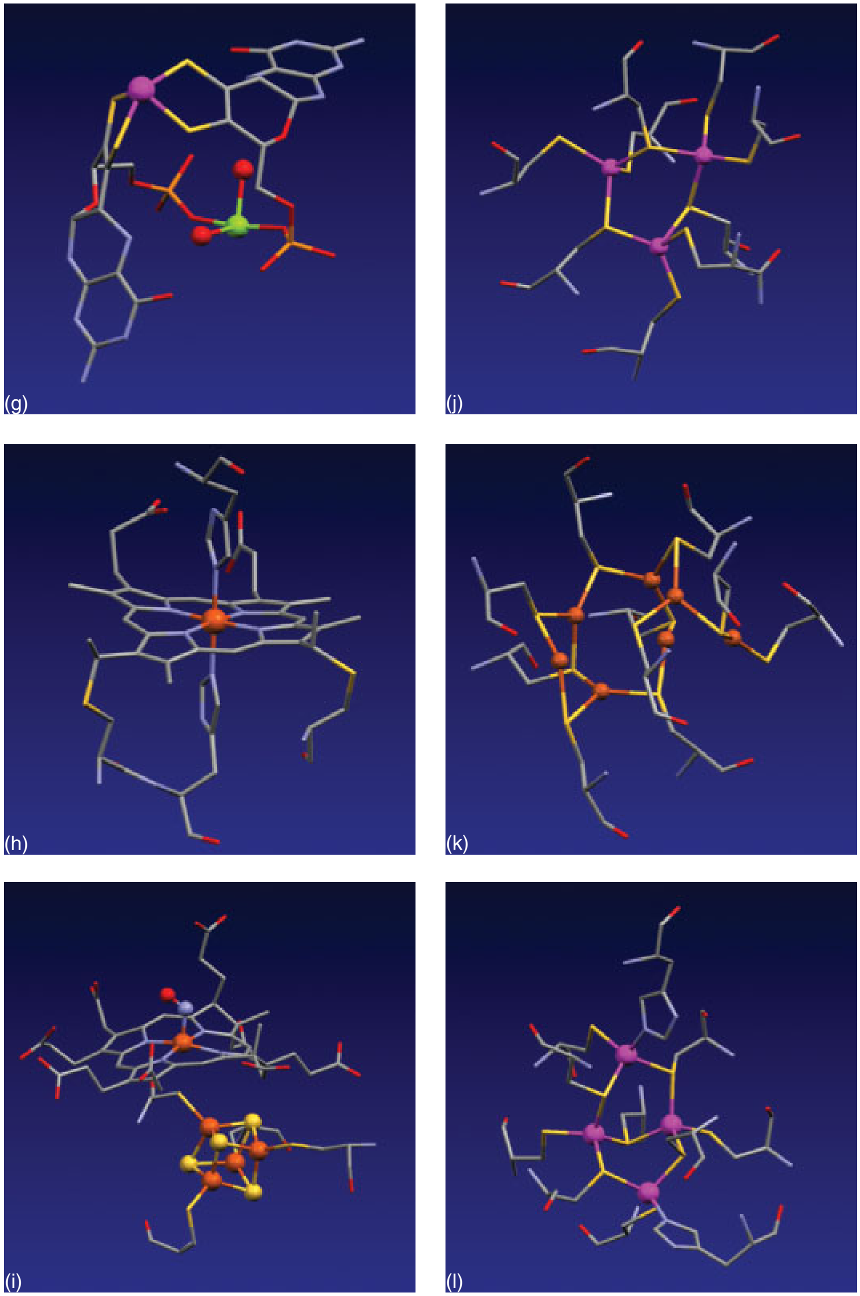

Figure 1 (*continued*) (g) Tungsten cofactor, W{Mg(H_2O)$_2$}(Dtpp)$_2$ of aldehyde ferredoxin oxidoreductase from *Pyrococcus furiosus* (PDB:1AOR). (h) Heme *c* 4 in cytochrome c_3 from *Desulfovibrio desulfuricans* (PDB:3CYR). (i) Siroheme–Fe_4S_4 center (NO complex) of sulfite reductase hemoprotein from *Escherichia coli* (PDB:6GEP). (j) Cd_3 cluster in metallothionein from *Notothenia coriiceps* (PDB:1M0J). (k) Cu_7 cluster in metallothionein from *Saccharomyces cerevisiae* (PDB:1AQR). (l) Zn_4 cluster in metallothionein from *Synechococcus sp*., PCC 7942 (PDB:1JJD)

oxidoreductase from *Desulfovibrio gigas* (PDB:1HLR) can de abbreviated as Mo(Dtpp-mCDP), and the tungsten cofactor of the aldehyde ferredoxin oxidoreductase from *Pyrococcus furiosus* (PDB:1AOR) as $W(Dtpp)_2$ (Figure 1g).

Methanol dehydrogenase (EC 1.1.99.8) and quinoprotein ethanol dehydrogenase (UniProt:Q9Z4J7) contain calcium complexes of pyrroloquinoline quinone (PQQ). Thiamine diphosphate (TPP), a cofactor of transketolase (EC 2.2.1.1), pyruvate dehydrogenase (EC 1.2.4.1), pyruvate:ferredoxin oxidoreductase (PDB:1B0P), and the pyruvate decarboxylase family (InterPro:IPR000399), binds Ca^{2+} or Mg^{2+} via its diphosphate group.

Metal–organic molecule complexes can form combined centers with mono-, di- or polynuclear inorganic centers. Examples include the siroheme–Fe_4S_4 center in sulfite reductase hemoprotein from *Escherichia coli* (Figure 1i), the Cu–S–Mo(Dtpp-mCDP) center in carbon monoxide dehydrogenase from *Oligotropha carboxidovorans* (PDB:1N5W), and the heme a_3–Cu_B center of ba_3-type cytochrome *c* oxidase from *Thermus thermophilus* (PDB:1EHK).

4. Gas storage and transport

After the advent of dioxygen (O_2) as a by-product of photosynthesis, living organisms had to solve a whole set of new problems: storage, transportation, sensing, detoxification, and utilization. Nature came up with at least three different solutions to the dioxygen storage/transport problem (Kurtz, 1999; Table 2). Note that the names of the oxygen transporters, "hemoglobin", "hemocyanin", and "hemerythrin", do not refer to the heme group (only found in globins), but are derived from the Greek word *αίμα* (blood).

4.1. Globins

Globins are heme-containing proteins involved in dioxygen binding and/or transport. One can say that the whole field of bioinorganic chemistry starts with globins. Hemoglobin was the first protein obtained in crystalline form by Hoppe-Seyler in 1864; a century later, the crystal structures of myoglobin (Figure 2a) and hemoglobin earned the Nobel Prize in Chemistry for Kendrew and Perutz. The globin superfamily includes vertebrate heterotetrameric ($\alpha_2\beta_2$) hemoglobins, vertebrate myoglobins, invertebrate globins (erythrocruorins and chlorocruorins), symbiotic plant globins (leghemoglobins), and bacterial and fungal flavohemoproteins (flavohemoglobins). Most globins contain a heme *b* (Fe–protoporphyrin-IX) group except for chlorocruorins, found in the blood of polychaete worms; their prosthetic group (chlorocruoroheme) is a derivative of the heme *b*, in which the vinyl group at position 2 is substituted by a formyl group.

The imidazole ring of the "proximal" histidine residue provides the fifth heme iron ligand. In most globins, the other axial heme iron position remains essentially free for O_2 coordination. O_2 binding (Figure 1d) results in a transition from

Table 2 Gas-binding proteins

Protein	Metal center	InterPro (UniProt)	PDB
Globins			
Hemoglobin	heme *b*	IPR002338, IPR002337	1A4F
Myoglobin	heme *b*	IPR002335	1MBO
Erythrocruorin	heme *b*	IPR002336	1ECD
Leghemoglobin	heme *b*	IPR001032	1GDI
Chlorocruorin	chlorocruoroheme	(Q26506)	
Indoleamine 2,3-dioxygenase-like myoglobin	heme *b*	(Q01966)	
Hemerythrin family			
Hemerythrin	Fe–Fe	IPR002063	1HMO
Myohemerythrin	Fe–Fe	IPR002063	1A7E
Hemocyanins			
Arthropod hemocyanin	Cu–Cu	IPR000896	1OXY
Molluscan hemocyanin	Cu–Cu		1JS8
Nitrophorins			
Rhodnius prolixus nitrophorin	heme *b*	IPR002351	1KOI
Cimex lectularius nitrophorin	heme *b*	(O76745)	
Gas sensors			
CO sensor CooA	heme *b*	(P72322)	1FT9
Soluble guanylate cyclase	heme *b*	IPR001054	
O_2 sensor FixL	heme *b*	IPR004358	1DP6
O_2 sensor FNR	Fe_4S_4	(P03019)	
Ethylene receptor ETR1	Cu	(P49333)	

high-spin to low-spin iron with accompanying changes in the Fe–N bond lengths and coordination geometry.

"Myoglobins" found in some gastropods do not belong to the globin superfamily but are homologous to the heme enzyme indoleamine 2,3-dioxygenase (EC 1.13.11.42) (Suzuki *et al*., 1998).

4.2. *Hemerythrin and myohemerythrin*

The *nonheme* iron proteins hemerythrin and myohemerythrin belong to a large group of diiron–carboxylate proteins. Hemerythrin has been isolated from the blood of marine invertebrates (annelids, brachiopods, and sipunculids). Hemerythrin typically exists as a homooctamer or heterooctamer composed of α- and β-type subunits of 13–14 kDa. Myohemerythrin is a monomeric O_2-binding protein found in the muscles of marine invertebrates. Hemerythrin and myohemerythrin possess one dinuclear iron center per subunit. The iron atoms are coordinated by five histidine residues and bridged by two carboxylate residues and a hydroxyl or oxo group (Figure 1e).

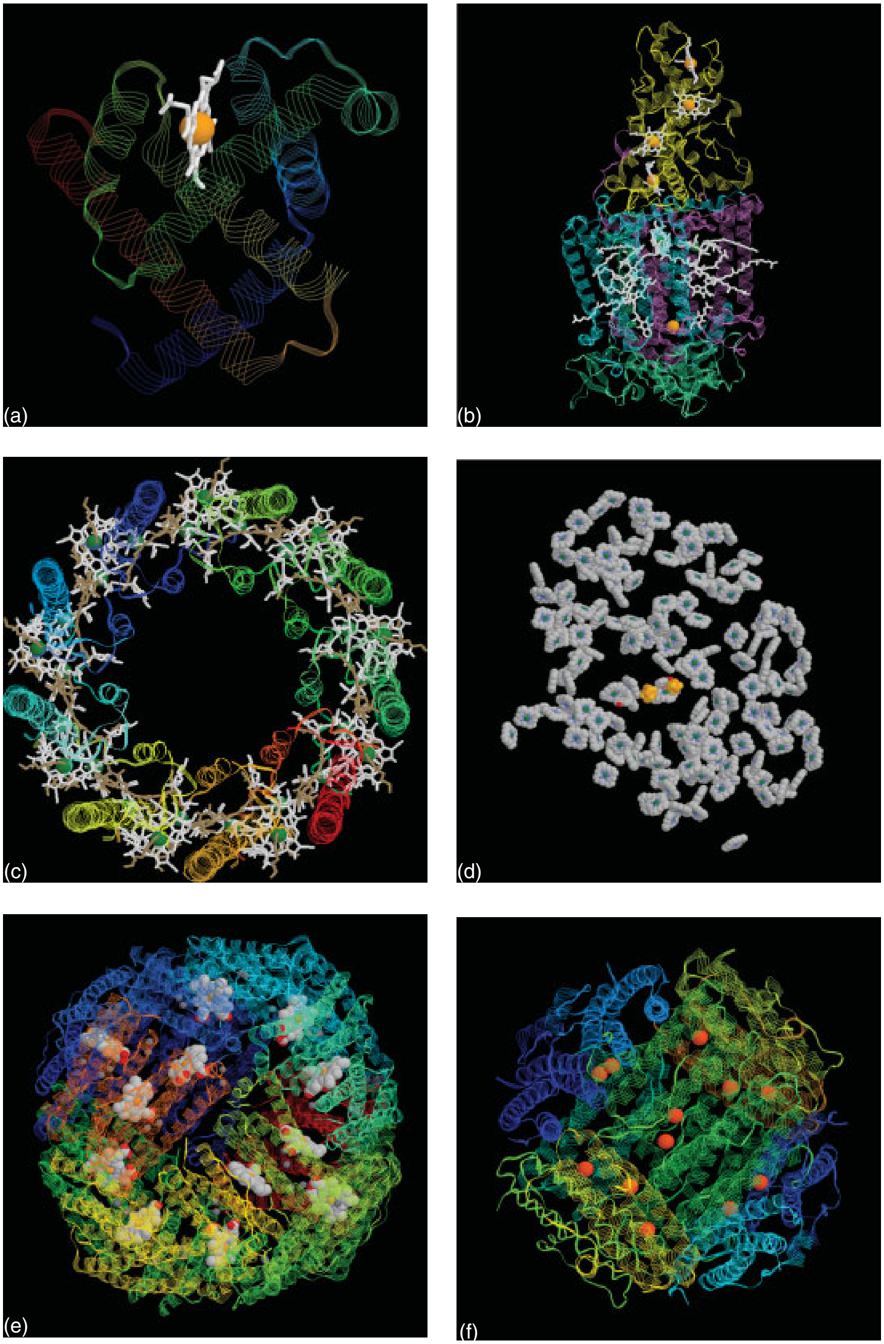

Figure 2 (a) Sperm whale myoglobin (PDB:1MBN). (b) Arrangement of cofactors in PRC from *Rhodopseudomonas viridis* (PDB:1PRC). (c) Light-harvesting complex 2 (B800-850) from *Rhodopseudomonas acidophila* (PDB:1KZU). (d) Arrangement of cofactors in PSI from *Pisum sativum* (PDB:1QZV). (e) Bacterioferritin from *Escherichia coli* (PDB:1BFR). (f) Dodecameric ferritin from *Listeria innocua* (PDB:1QGH)

4.3. Hemocyanins

Hemocyanins are the copper-containing oxygen transport proteins found in some arthropods and molluscs. Deoxyhemocyanin contains a dinuclear Cu^{+}–Cu^{+} center and is colorless. Upon oxygenation, the copper center is oxidized to Cu^{2+}–Cu^{2+} (dioxygen is bound as ${O_2}^{2-}$) and the protein becomes blue. At the level of primary, tertiary, and quaternary structure, arthropod and molluscan hemocyanins show significant differences. Arthropod hemocyanins exist as hexamers or oligo(hexamers) of similar polypeptides. Each ~75-kDa monomer consists of three structural domains; the central, mostly helical domain binds copper. Molluscan hemocyanins are hollow cylindrical decamers, dodecamers, or oligo(decamers) of large (~450 kDa) subunits. Each subunit consists of seven or eight globular "functional units" of ~400 residues containing one dinuclear copper site.

In spite of the great differences, the active sites of arthropod and molluscan hemocyanins are remarkably similar. This may be indicative of their distant relationship (van Holde *et al*., 2001). The oxygen-binding site contains two copper atoms, each coordinated by three histidine residues (Figure 1f). In molluscan hemocyanins, a thioether bridge is formed between one of the copper ligating histidines and an adjacent cysteine residue.

4.4. Nitrophorins

Dioxygen is not the only gas to have specific transporters. For instance, nitric oxide (NO) is transported by the nitrophorins, hemoproteins found in the saliva of blood-feeding insects. Two unrelated classes of nitrophorins are described. The saliva of the blood-sucking bug *Rhodnius prolixus* contains four homologous nitrophorins, designated NP1 to NP4 in order of their relative abundance in the glands. As isolated, nitrophorins contain NO ligated to the heme iron(III). Histamine, which is released by the host in response to tissue damage, is another nitrophorin ligand. Nitrophorins transport NO to the feeding site. Dilution, binding of histamine, and increase in pH (from pH ~5 in the salivary gland to pH ~7.4 in the host tissue) facilitate the release of NO into the tissue where it induces vasodilatation. Crystal structures of *R. prolixus* nitrophorins reveal a lipocalin-like fold.

The salivary nitrophorin from the hemipteran *Cimex lectularius* is a heme–thiolate protein that has no sequence similarity to *R. prolixus* nitrophorins. Apparently, the two classes of insect nitrophorins have arisen as a product of convergent evolution.

5. Gas sensors

A number of hemoproteins evolved to function as sensors for O_2, CO, and NO. Among them are the NO receptor soluble guanylate cyclase (EC 4.6.1.2), the O_2 sensor/histidine kinase FixL, and the CO-sensing transcriptional activator CooA (Rodgers, 1999). Nonheme gas sensors include fumarate and nitrate reduction (FNR) regulatory protein (Kiley and Beinert, 1998).

5.1. *CO sensor CooA*

The CO-sensing transcriptional activator CooA is found in the bacterium *Rhodospirillum rubrum* that can grow using CO as the sole energy source. CooA regulates the CO-dependent expression of the *coo* operon (EMBL:U65510) genes, including carbon monoxide dehydrogenase (EC 1.2.99.2) and hydrogenase (EC 1.12.7.2). CooA is a homodimer with each monomer consisting of a heme sensor and DNA-binding domains. Only CO-bound CooA binds to its target DNA. The unique features of CooA include ligation of the heme iron by the N-terminal proline residue and exchange of the axial ligands upon oxidation. The heme in CooA is hexacoordinate, with axial ligands Cys-75 and Pro-2 (Fe^{3+}), His-77 and Pro-2 (Fe^{2+}), and His-77 and CO (Fe^{2+}–CO) (Aono, 2003).

6. Metalloenzymes

The crystallization of urease (EC 3.5.1.5) by James Sumner in 1926 provided firm proof of the protein nature of enzymes and brought him the Nobel Prize in Chemistry 20 years later. However, it was not until 1975 that it was revealed that the active site of this enzyme contains two nickel atoms (Karplus *et al*., 1997).

Metalloproteins are present in all six enzyme classes (Table 3). Magnesium-dependent enzymes are probably the most abundant, which is not surprising given that Mg^{2+} is the most abundant divalent cellular cation (Maguire and Cowan, 2002). Mg^{2+} may be a part of the substrate (e.g., Mg^{2+}–isocitrate complex is *the* substrate of isocitrate lyase, EC 4.1.3.1) or serves as a cofactor, as in the dinuclear center of restriction endonuclease *Eco*RV (UniProt:P04390) (Cowan, 2002). Magnesium and zinc ions function as Lewis acids toward substrates. Arguably, oxidoreductases (EC 1) are the most interesting enzyme class for the bioinorganic chemist since they show the greatest diversity of metal centers. Transition metals such as V, Mn, Fe, Co, Ni, Cu, Mo, and W are used in the redox-active centers of oxidoreductases. However, they are also found in the active sites of nonredox enzymes, for example, Co or Mn centers in metalloproteinases (*see* Article 80, **Peptidases, families, and clans**, Volume 6).

Manganese and copper enzymes contain a variety of inorganic (mono-, di-, and polynuclear) centers. Iron, cobalt, and nickel enzymes contain both inorganic centers and tetrapyrrole complexes (hemes, cobamide, and coenzyme F430). Mn, Fe, Ni, Cu, and Zn are found in heterodinuclear and heteropolynuclear centers. With the notable exception of the molybdenum–iron–sulfur cofactor (FeMoco) of molybdenum nitrogenase (UniProt:P07328), molybdenum and tungsten enzymes bind metal–Dtpp or metal–$Dtpp_2$ complexes. Vanadium is present in the vanadium–iron–sulfur cluster of vanadium nitrogenase (UniProt:P16855) or as vanadate (VO_4^{3-}) in vanadium haloperoxidases (InterPro:IPR008934). Until recently, cadmium has been considered only as a toxic metal; however, it has been shown to be a physiological cofactor of the carbonic anhydrase (EC 4.2.1.1) from the marine diatom *Thalassiosira weissflogii* (Lane and Morel, 2000).

Table 3 Examples of structurally characterized metalloenzymes

EC	Enzyme name	Cofactor	PDB
1.1.1.1	Alcohol dehydrogenase	Zn	2OHX
1.1.99.8	Methanol dehydrogenase	Ca-PQQ	1G72
1.1.3.22	Xanthine oxidase	Mo(Dtpp-mP), FAD, Fe_2S_2,	1FIQ
1.2.1.2	Formate dehydrogenase	Mo(Dtpp-mGDP), Fe_4S_4, heme	1KQF
1.2.4.1	Pyruvate dehydrogenase	Mg–TPP	1L8A
1.2.4.4	2-oxoisovalerate dehydrogenase	Mg–TPP	1QS0
1.2.7.1	Pyruvate:ferredoxin oxidoreductase	Mg–TPP, Fe_4S_4	1B0P
1.2.7.5	Formaldehyde ferredoxin oxidoreductase $W(Dtpp)_2$	Mg–$W(Dtpp)_2$, Fe_4S_4	1B4N
1.2.99.2	Carbon monoxide dehydrogenase	Fe_4S_4, $NiFe_3S_4$	1JQK
1.2.99.2	Carbon monoxide dehydrogenase	Fe_4S_4, $NiFe_4S_5$	1JJY
1.2.99.2	Carbon monoxide dehydrogenase	FAD, Fe_2S_2, Cu-S-Mo(Dtpp-mCDP)	1N5W
1.3.99.1	Fumarate reductase	FAD, Fe_2S_2, Fe_3S_4, Fe_4S_4	1KF6
1.4.3.6	Amine oxidase (copper-containing)	Cu, TPQ	1OAC
1.4.3.13	Protein-lysine 6-oxidase	Cu, TPQ, Ca^{2+}	1N9E
1.4.99.4	Aralkylamine dehydrogenase	heme *c*, CTQ	1JJU
1.7.2.1	Nitrite reductase (NO-forming)	Cu	1OE1
1.7.2.1	Nitrite reductase (NO-forming)	hemes *c* and d_1	1QKS
1.7.3.4	Hydroxylamine oxidase	hemes *c* and P460	1FGJ
1.7.99.6	Nitrous-oxide reductase	Cu–Cu, Cu_4S	1QNI
1.8.1.2	Sulfite reductase (NADPH)	siroheme–Fe_4S_4, FAD, FMN	1AOP
1.8.3.1	Sulfite oxidase	Mo(Dtpp-mP), heme	1SOX
1.9.3.1	Cytochrome-*c* oxidase (aa_3-type)	Cu–Cu, heme *a*, heme *a*–Cu, Mg^{2+}	2OCC
1.9.3.1	Cytochrome-*c* oxidase (ba_3-type)	Cu–Cu, heme *b*, heme a_s–Cu	1EHK
1.10.2.2	Ubiquinol–cytochrome-*c* reductase (cytochrome bc_1 complex)	Fe_2S_2, hemes *b* and *c*	1EZV
1.10.99.1	Plastoquinol–plastocyanin reductase (cytochrome b_6f complex)	Fe_2S_2, hemes *b* and *c*, Chl-*a*	1Q90 1VF5
1.11.1.5	Cytochrome-*c* peroxidase	heme *b*	1EBE
1.11.1.6	Catalase	heme *b*	1GWH
1.11.1.6	Catalase	Mn–Mn	1JKU
1.11.1.7	Myeloperoxidase	heme *m*	1D2V
1.11.1.10	Chloride peroxidase	heme *b*	2CPO
1.11.1.10	Chloride peroxidase	VO_4^{3-}	1IDQ
1.11.1.11	L-Ascorbate peroxidase	heme *b*	1OAF
1.11.1.13	Manganese peroxidase	heme *b*	1MNP
1.11.1.14	Diarylpropane peroxidase	heme *b*	1B80
1.14.13.25	Methane monooxygenase hydroxylase	Fe–Fe	1MTY
1.14.13.39	Nitric oxide synthase	heme *b*, FAD, FMN, tetrahydrobiopterin, Zn^{2+}	1NSE
1.14.19.2	Acyl-[acyl-carrier-protein] desaturase	Fe–Fe	1OQ9
1.14.20.1	Deacetoxycephalosporin-C synthase	Fe^{2+}	1UOG
1.14.99.1	Prostaglandin-endoperoxide synthase	heme *b*	1CVU
1.15.1.1	Superoxide dismutase	Cu–Zn	1XSO
1.15.1.1	Superoxide dismutase	Fe	1ISA
1.15.1.1	Superoxide dismutase	Mn	1D5N
1.15.1.2	Superoxide reductase	Fe	1DQI
1.17.4.2	Ribonucleoside-triphosphate reductase (Class I)	Fe–Fe	1MXR
1.17.4.2	Ribonucleoside-triphosphate reductase (Class II)	B_{12}	1L1L
1.17.4.2	Ribonucleoside-triphosphate reductase (Class III)	Fe_4S_4	

(*continued overleaf*)

Table 3 (*continued*)

EC	Enzyme name	Cofactor	PDB
1.18.6.1	Nitrogenase (molybdenum)	FeMoco, Fe_8S_7, Fe_4S_4	1N2C
1.12.7.2	Hydrogenase (nickel–iron)	Ni–Fe, Fe_3S_4, Fe_4S_4	1H2A
1.12.7.2	Hydrogenase (iron)	Fe–Fe, Fe_2S_2, Fe_4S_4	1FEH

4.99.1.1	Ferrochelatase	Fe_2S_2	1HRK
5.1.3.4	L-Ribulose-phosphate 4-epimerase	Zn^{2+}	1JDI
5.1.99.1	Methylmalonyl-CoA epimerase	Co^{2+}	1JC5
5.3.1.5	Xylose isomerase	Co–Co	1A0C
5.3.1.5	Xylose isomerase	Mn–Mn	1A0D
5.3.3.2	Isopentenyl-diphosphate D-isomerase	Mn^{2+}	1I9A
5.4.2.2	Phosphoglucomutase	Mg^{2+}	3PMG
5.4.2.6	β-Phosphoglucomutase	Mg^{2+}	1O08
5.4.99.1	Methylaspartate mutase	pseudo-B_{12}	1I9C
5.4.99.2	Methylmalonyl-CoA mutase	B_{12}	4REQ
5.5.1.7	Chloromuconate cycloisomerase	Mn^{2+}	2CHR
5.5.1.8	Geranyl-diphosphate cyclase	Mg^{2+}	1N1B
6.1.1.10	Methionine–tRNA ligase	Zn^{2+}	1F4L
6.3.1.2	Glutamate–ammonia ligase	Mn–Mn	1F52
6.3.5.5	Carbamoyl-phosphate synthase (glutamine-hydrolyzing)	Mn	1CE8
6.5.1.2	DNA ligase (NAD^+)	Zn^{2+}	1DGS

Some metal sites in enzymes are not involved in catalytic activity but play structural or regulatory roles; other metal sites facilitate electron transfer and are therefore analogous to those of electron-transfer proteins.

Here, I will only briefly dwell on two groups of metalloenzymes: the superoxide dismutase and P450 enzymes, which perfectly illustrate convergent and divergent evolution of biological catalysts.

6.1. *Superoxide dismutase*

The same biochemical problem could be presented with several metalloenzyme solutions. Superoxide dismutase (SOD; EC 1.15.1.1) catalyzes the redox disproportionation (dismutation) of the superoxide radical, $O_2^{\bullet-}$:

$$O_2^{\bullet-} + O_2^{\bullet-} + 2H^+ \rightarrow O_2 + H_2O_2 \quad (1)$$

Several groups of SODs are known, distinguished by the metal prosthetic group: Cu–Zn, Fe, Mn, and Ni.

Fe- and Mn-SODs constitute a structural family (InterPro:IPR001189). Fe- and Mn-SODs are unequally distributed throughout the kingdoms of living organisms and are located in different cellular compartments. Fe-SOD and Mn-SOD from some organisms (e.g., *E. coli*) exhibit almost absolute metal specificity, while other enzymes, such as "cambialistic" SOD from *Propionibacterium shermanii* (UniProt:P80293), are active with either metal. A variation on this theme is Fe,Zn-SOD from *Streptomyces coelicolor* (UniProt:O51917) that apparently contains an extra zinc-binding center. The active-site metal (Fe or Mn) is pentacoordinate, with the metal ligands (N^{ε} of three conserved histidine residues, O^{δ} of the conserved aspartic acid residue, and a water molecule) arranged in a distorted trigonal bipyramidal geometry (Figure 1b).

Cu,Zn-SOD (InterPro:IPR001424) is found in the cytosol of eukaryotic cells and in the periplasm of different gram-negative bacteria. The active site contains Cu, coordinated by four histidine ligands and a water molecule in a distorted square planar geometry, and Zn ligated by one aspartic acid and three histidine residues in a tetrahedral geometry. The two metal atoms are bridged by the imidazole ring of one histidine residue (Figure 1c).

Neelaredoxin from *D. gigas* (UniProt:O50258) is a mononuclear iron SOD, unrelated to the Fe/Mn-SOD family but homologous to the superoxide reductase from *P. furiosus* (UniProt:P82385). Ni-SOD are found in *Streptomyces seoulensis* (UniProt:P80734) and *S. coelicolor* (UniProt:P80735).

6.2. *P450 enzymes*

P450 enzymes (P450s), also known as cytochromes P450, constitute a superfamily of heme–thiolate proteins, widely distributed throughout all kingdoms of life. The animal genomes contain ~80–90 P450 genes and higher plant genomes contain up to 300 genes, while many bacterial species contain only one P450 gene. Of all known heme–thiolate enzymes (and heme enzymes in general), the P450s are by far the most functionally diverse. Usually, they act as terminal

oxidases in multicomponent electron-transfer chains, called P450-containing systems. Eukaryotic microsomal P450s and some bacterial P450s receive electrons from an FAD- and FMN-containing enzyme, NADPH:P450 reductase (CPR; EC 1.6.2.4). The microsomal CPR is a membrane-bound protein that interacts with different P450s. In *Bacillus megaterium* (UniProt:P14779) and *Bacillus subtilis* (UniProt:O08394; UniProt:O08336), CPR is a C-terminal domain of CYP102, a single polypeptide self-sufficient soluble P450 system.

Cytochrome b_5 (InterPro:IPR001199) can serve as an effector (activator or inhibitor) of some P450s. One (of several) hypotheses is that cytochrome b_5 is involved in the transfer of the second electron to P450, either from CPR or NADH:cytochrome b_5 reductase (EC 1.6.2.2) (Schenkman and Jansson, 2003).

Mitochondrial P450s, such as the steroid 11β-monooxygenase (EC 1.14.15.4) and the cholesterol monooxygenase (side-chain-cleaving) (EC 1.14.15.6), and bacterial P450s like the camphor 5-monooxygenase (EC 1.14.15.1) are reduced by small soluble Fe_2S_2 proteins of the adrenodoxin family (InterPro:IPR001055). In turn, adrenodoxin and its bacterial homologs are reduced by corresponding FAD-containing reductases.

A novel class of self-sufficient P450 monooxygenases has been recently described (De Mot and Parret, 2002), exemplified by P450 RhF from *Rhodococcus* sp. (UniProt:Q8KU27). This protein contains an Fe_2S_2 and FMN-binding domain homologous to phthalate oxygenase reductase (InterPro:IPR000951) fused to the N-terminal P450 domain.

The most common reaction catalyzed by P450 enzymes is a monooxygenase reaction, that is, insertion of one atom of oxygen into the substrate while the other oxygen atom is reduced to water:

$$RH + O_2 + 2H^+ + 2e^- \rightarrow ROH + H_2O \qquad (2)$$

Many P450 monooxygenases, including most drug-metabolizing enzymes, are historically classified as "unspecific monooxygenase" (EC 1.14.14.1), although the specificity varies immensely between different P450 forms.

Some P450s do not require any other protein components for their function. Nitric oxide reductase (CYP55, P450nor) is involved in denitrification in several fungal species. This enzyme does not possess monooxygenase activity but is able to reduce NO to form nitrous oxide (N_2O) directly using NAD(P)H as electron donor. Allene oxide synthase (EC 4.2.1.92), prostacyclin synthase (EC 5.3.99.4), and thromboxane synthase (EC 5.3.99.5) are examples of P450s that do not require either NAD(P)H or molecular oxygen for their catalytic activity. Substrates for all these enzymes are fatty acid derivatives containing partially reduced dioxygen (as either hydroperoxy or epidioxy groups).

7. Electron-transfer metalloproteins

Although many transition metals are found in metalloproteins, only iron and copper are used in the pure electron transferases. These include mononuclear copper

Table 4 Structurally characterized electron-transfer metalloproteins

Protein	Metal center	InterPro (UniProt)	PDB
Mononuclear copper proteins (Cupredoxins)		IPR008972	
Azurin	$Cu(N^{\delta}{}_{His})_2(O_{Gly})(S^{\delta}{}_{Met})(S^{\gamma}{}_{Cys})$	IPR003246	2AZA
Amicyanin	$Cu(N^{\delta}{}_{His})_2(S^{\delta}{}_{Met})(S^{\gamma}{}_{Cys})$	IPR002386	1AAC
Plastocyanin	$Cu(N^{\delta}{}_{His})_2(S^{\delta}{}_{Met})(S^{\gamma}{}_{Cys})$	IPR002387	1PLC
Stellacyanin	$Cu(N^{\delta}{}_{His})_2(O^{\varepsilon}{}_{Gln})(S^{\gamma}{}_{Cys})$	(P29602)	1JER

Cytochromes			
Cytochrome *b*	$Fe(por)(N^{\varepsilon}{}_{His})_2$	IPR005797	1BCC
Cytochrome b_6	$Fe(por)(N^{\varepsilon}{}_{His})_2$	IPR005797	1VF5
Cytochrome b_5	$Fe(por)(N^{\varepsilon}{}_{His})_2$	IPR001199	1CYO
Cytochrome b_{562}	$Fe(por)(N^{\varepsilon}{}_{His})(S^{\delta}{}_{Met})$	(P00192)	256B
Class I (mitochondrial-type) cytochromes *c*	$Fe(por)(N^{\varepsilon}{}_{His})(S^{\delta}{}_{Met})$	IPR003088	1HRC
Class IIb cytochrome *c*	$Fe(por)(N^{\varepsilon}{}_{His})(S^{\delta}{}_{Met})$	(P00150)	
Class III (bacterial-type) multiheme cytochromes *c*	$Fe(por)(N^{\varepsilon}{}_{His})_2$	IPR002322	1I77 1HH5 19HC
Class IV (photosynthetic reaction center) multiheme cytochrome *c*	$Fe(por)(N^{\varepsilon}{}_{His})(S^{\delta}{}_{Met})$, $Fe(por)(N^{\varepsilon}{}_{His})_2$	IPR003158	1DXR
Cytochrome c_{554}	$Fe(por)(N^{\delta}{}_{His})(N^{\varepsilon}{}_{His})$, $Fe(por)(N^{\varepsilon}{}_{His})$, $Fe(por)(N^{\varepsilon}{}_{His})_2$	(Q57142)	1FT5
Cytochrome c_1	$Fe(por)(N^{\varepsilon}{}_{His})(S^{\delta}{}_{Met})$	IPR002326	1BGY
Cytochrome *f*	$Fe(por)(N^{\alpha}{}_{Tyr})(N^{\varepsilon}{}_{His})$	IPR002325	1CI3

proteins (cupredoxins), the mononuclear iron proteins rubredoxin and desulforedoxin, iron–sulfur proteins (ferredoxins), and heme proteins (cytochromes) (Table 4).

7.1. Cytochromes

Cytochromes can be defined as electron- or proton-transfer proteins having one or several heme groups. Cytochromes possess a wide range of properties and function in a large number of different redox processes. Cytochromes can be classified according to their heme iron coordination, by heme type, and further by sequence

similarity. In contrast to other heme proteins, the heme iron in cytochromes is coordinated with two endogenous ligands in both reduced and oxidized states.

Cytochromes *b* can be defined as electron-transfer proteins having one or two heme *b* groups, noncovalently bound to the protein. Some hemoproteins, such as P450s and nitric oxide synthase (NOS), have been termed "cytochromes" as well (Kiel, 1995). Although both P450s and NOS can be considered as *b*-type cytochromes, their main function is catalysis.

Cytochromes b_5 are ubiquitous electron-transfer proteins found in animals, plants, fungi, and purple phototrophic bacteria. The microsomal and mitochondrial variants are membrane-bound, while bacterial ones and those from erythrocytes and other animal tissues are water-soluble. The eukaryotic microsomal cytochrome b_5 is an electron donor for stearoyl-CoA 9-desaturase (EC 1.14.19.1), linoleoyl-CoA desaturase (EC 1.14.19.13) and a number of P450 monooxygenases (Schenkman and Jansson, 2003).

Diheme cytochromes *b* include the cytochrome *b* subunit of the cytochrome bc_1 complex (ubiquinol–cytochrome-*c* reductase, EC 1.10.2.2) and the cytochrome b_6 subunit of the cytochrome b_6f complex (plastoquinol–plastocyanin reductase, EC 1.10.99.1).

Cytochromes *c* (InterPro:IPR000345) have one or more hemes bound to the protein by one or, more commonly, two thioether bonds involving sulfhydryl groups of cysteine residues. The fifth heme iron ligand is always provided by a histidine residue. Ambler (1991) recognized four classes of cytochromes *c*:

Class I includes the low-spin soluble cytochrome *c* of mitochondria and bacteria, with the heme-attachment site toward the N-terminus, and the sixth ligand provided by a methionine residue about 40 residues further on toward the C-terminus. Mitochondrial cytochrome *c* is among the most studied proteins. Since many eukaryotes have only one mitochondrial cytochrome *c*, the amino acid sequence comparison of Class I cytochromes *c* has been a natural choice for phylogenetic analysis since the 1960s. More recently, the key role of the cytochrome *c* in regulation of programmed cell death has been realized (Hancock *et al*., 2001).

Class II are four-α-helix bundle proteins that include the high-spin cytochrome c' (Class IIa; probably involved in gas sensing, not electron transfer) and a number of low-spin cytochromes (Class IIb), for example, cytochrome *c*-556 (Bertini *et al*., 2004). The heme-attachment site is close to the C-terminus.

Class III comprises the low redox potential multiple-heme cytochromes: triheme (cytochrome c_7), tetraheme (cytochrome c_3), nonaheme, and hexadecaheme (high-molecular-weight cytochrome, HMC), with only 30–40 residues per heme group. The hemes are all bis-His coordinated (Figure 1h), except for one high-spin heme in HMC, which is mono-His coordinated.

Class IV was originally created to hold the complex proteins that have other prosthetic groups as well as heme *c*, for example, flavocytochrome *c* and cytochrome cd_1. Alternatively, Moore and Pettigrew (1990) have suggested that Class IV includes tetraheme proteins containing both bis-His and His-Met coordinated hemes, with a 3D structure exemplified by that of the cytochrome *c* subunit of the photosynthetic reaction center (PRC), and which form a structurally homogeneous family.

Many other cytochromes *c* that do not belong to the classes I–IV are known. Among them are the cytochrome c_1 subunit of the cytochrome bc_1 complex, the cytochrome *f* subunit of the cytochrome b_6f complex, and the tetraheme cytochrome c_{554} from *Nitrosomonas europaea*. A number of oxidoreductases contain one or more hemes *c*: diheme cytochrome cd_1 nitrite reductase (EC 1.7.2.1), tetraheme flavocytochrome c_3 fumarate reductase (EC 1.3.99.1), pentaheme cytochrome *c* nitrite reductase (EC 1.7.2.2), and octaheme hydroxylamine oxidoreductase (EC 1.7.3.4).

7.2. *Rubredoxin and desulforedoxin*

In the $Fe(Cys)_4$ proteins, tetracoordinate iron is bound to four cysteine residues; these proteins, which are involved in electron transfer, contain the simplest form of an iron center. $Fe(Cys)_4$ proteins are often (incorrectly) included in the group of iron–sulfur proteins even though they do not bind inorganic sulfur.

Rubredoxin is a low-molecular-weight iron-containing bacterial protein involved in electron transfer, for example, as an electron donor in alkane 1-monooxygenase (EC 1.14.15.3) and superoxide reductase (EC 1.15.1.2) systems. In rubredoxin, iron is tetrahedrally coordinated. Desulforedoxin represents another class of $Fe(Cys)_4$ proteins with a distorted tetrahedral coordination of the iron. The distortion arises from adjacent cysteine residues in the sequence of desulforedoxin. In desulforedoxin mutants with one or two amino acid residues inserted between the two adjacent cysteines, the metal centers become spectroscopically and structurally similar to that of rubredoxin (Goodfellow *et al*., 2003).

7.3. *Ferredoxins*

Ferredoxins are iron–sulfur proteins that mediate electron transfer in a range of metabolic reactions; they fall into several subgroups according to the nature of their iron–sulfur cluster(s). One group, originally found in the bacterium *Clostridium pasteurianum*, has been termed “bacterial-type”, in which the active center is an Fe_4S_4 cluster. Bacterial-type ferredoxins may in turn be subdivided into further groups, on the basis of their sequence properties. Most contain at least one conserved domain, including four cysteine residues that bind an Fe_4S_4 cluster (InterPro:IPR001450). In some bacterial-type ferredoxins, one of the four conserved cysteine residues is lost. These ferredoxins bind an Fe_3S_4 cluster instead of an Fe_4S_4 cluster. In *P. furiosus*, Fe_4S_4 ferredoxin (UniProt:P29603), one of the conserved cysteine residues is substituted with an aspartic acid. During the evolution of bacterial-type ferredoxins, intrasequence gene duplication, transposition and fusion events occurred, resulting in the appearance of proteins with multiple iron–sulfur centers, such as dicluster $(Fe_4S_4)(Fe_4S_4)$ and $(Fe_3S_4)(Fe_4S_4)$ ferredoxins, polyferredoxins, and iron–sulfur subunits of various bacterial oxidoreductases.

High potential iron proteins (HiPIPs) form a unique family of Fe_4S_4 ferredoxins that function in anaerobic electron-transport chains. Some HiPIPs have a redox

potential higher than any other known iron–sulfur protein; for instance, HiPIP from *Rhodospirillum salinarum* has a redox potential of 500 mV (Heering *et al*., 1995). The iron–sulfur cluster in HiPIP accepts $(Fe_4S_4)^{2+}$ and $(Fe_4S_4)^{3+}$ oxidation states, while (Fe_4S_4) clusters of "bacterial-type" ferredoxins cycle between $(Fe_4S_4)^+$ and $(Fe_4S_4)^{2+}$ oxidation states.

The group of ferredoxins originally found in chloroplast membranes has been termed "chloroplast-type" or "plant-type". Another group, exemplified by the mitochondrial protein adrenodoxin, has been termed "mitochondrial-type" although homologous proteins were found in bacteria. In both "chloroplast-type" and "mitochondrial-type" ferredoxins, the active center is an Fe_2S_2 cluster, where the irons are tetrahedrally coordinated both by inorganic sulfurs and by sulfurs provided by four conserved cysteine residues.

In chloroplasts, Fe_2S_2 ferredoxins function as electron carriers in the photosynthetic electron-transport chain and as electron donors to various cellular proteins, such as glutamate synthase (EC 1.4.7.1), nitrate reductase (EC 1.7.7.2), and sulfite reductase (EC 1.8.7.1). In hydroxylating bacterial dioxygenase systems, they serve as intermediate electron-transfer carriers between reductase flavoproteins and an oxygenase (Mason and Cammack, 1992). In mitochondrial monooxygenase systems, adrenodoxin transfers an electron from NADPH:adrenodoxin reductase to a membrane-bound P450. In bacteria, putidaredoxin and terpredoxin serve as electron carriers between corresponding NADH-dependent ferredoxin reductases and soluble P450.

The Fe_2S_2 clusters of the Rieske proteins of electron-transfer chains (cytochrome bc_1 and cytochrome b_6f complexes) and of the ferredoxin component of aromatic-ring-hydroxylating dioxygenases such as benzene 1,2-dioxygenase (EC 1.14.12.3), toluene 1,2-dioxygenase (EC 1.14.12.11), naphthalene 1,2-dioxygenase (EC 1.14.12.12), and toluene 1,2-dioxygenase (EC 1.14.12.11) have similar chemical structures (Mason and Cammack, 1992). The Fe_2S_2 cluster is coordinated by two cysteine and two histidine residues.

7.4. *Cupredoxins*

In contrast to cytochromes and ferredoxins, all known copper electron-transfer proteins belong to one superfamily (InterPro:IPR008972). They contain a so-called "type I" mononuclear copper center with absorption at ~600 nm, which gives rise to the characteristic blue color (hence the names "azurin", "-cyanin" and the collective term for type I proteins, "blue copper proteins"). The common structural feature of type I Cu centers is two imidazole nitrogens and one thiolate sulfur (Gray *et al*., 2000). Cupredoxins are found in all kingdoms of life and participate in a variety of electron-transfer processes.

Plastocyanin mediates the electron transfer from the cytochrome b_6f complex to the photosystem I (PSI). It has been proposed that, with increasing bioavailability of copper, plastocyanin has evolved to replace its functional analog, Class I cytochrome c called cytochrome c_6. The cyanobacteria and algae are able to synthesize both plastocyanin and cytochrome c_6 depending on the bioavailabilities of copper and iron, respectively (Hervás *et al*., 2003).

8. Photosynthetic metalloproteins

Chlorophylls represent a group of tetrapyrrole pigments found in photosynthetic organisms that contain magnesium as the centrally chelated metal and contain a fifth five-membered ring E. Two functional classes of the protein–chlorophyll complexes may be defined: antenna systems (light-harvesting complexes) and photosynthetic reaction centers (PRCs) (Table 5). The antenna complexes broaden the spectral region of the light that can be used for photosynthesis and transfer the excitation energy from one to another and to the reaction center. With the exception of the Fenna–Matthews–Olson complex, all photosynthetic proteins reviewed here

Table 5 Structurally characterized chlorophyll proteins

are multisubunit transmembrane complexes (*see* Article 42, **Membrane-anchored protein complexes**, Volume 5).

8.1. Fenna–Matthews–Olson complex

Green sulfur bacteria (Chlorobiaceae) contain iron–sulfur type reaction centers and a large peripheral antenna complex called a *chlorosome*. The chlorosome collects light energy and transfers it to the membrane-bound reaction center through the amphypathic Fenna–Matthews–Olson (FMO) complex, also known as bacteriochlorophyll *a* (BChl-*a*) protein. The structure of the FMO complex from *Prosthecochloris aestuarii* was the first antenna structure to be solved. The complex consists of three identical subunits binding seven BChl-*a* molecules each. The magnesium of BChl-*a* is pentacoordinate; BChls 1, 3, 4, 6, and 7 are ligated by histidine residues, BChl 5 is coordinated to the backbone oxygen of leucine, while a bound water molecule serves as a ligand for BChl 2.

8.2. Light-harvesting complexes of purple bacteria

The photosynthetic antenna systems collect and deliver excited-state energy through excitation transfer to the reaction center. Photosynthetic purple bacteria have up to three types of antenna, or light-harvesting (LH), complexes besides the reaction center. LH1 complexes are closely associated with the reaction center and form a "core" complex, while LH2 and LH3 complexes are peripheral to the "core". The peripheral complexes have absorption maxima at shorter wavelengths than LH1 and the reaction center.

The LHs from purple bacteria are oligomers with the $\alpha\beta$ heterodimer as a basic unit. In LH2 and LH3, the $\alpha\beta$ heterodimers bind three bacteriochlorophyll *a* (BChl-*a*) molecules and at least one molecule of carotenoid. The role of the carotenoids in LH2 is twofold: they absorb light in the visible region of the spectrum and transfer it to BChl-*a* (accessory light-harvesting) and protect the LH2 from damage by singlet oxygen species (Isaacs *et al*., 1995). The $\alpha\beta$ heterodimers are arranged in a ring-shaped aggregate with strict rotational symmetry. The α- and β-subunits each possess single transmembrane helices, which are arranged in two concentric rings where the α-subunits form the inner circle and the β-subunits form the outer one. However, *Rs. molischianum* LH2 exists as an $(\alpha\beta)_8$ complex with eightfold symmetry, whereas *Rps. acidophila* LH2 and LH3 are $(\alpha\beta)_9$ complexes with ninefold symmetry (Figure 2c).

8.3. Photosynthetic reaction centers of purple bacteria

Photosynthetic reaction centers (PRCs) are membrane-spanning complexes of polypeptide chains and cofactors that catalyze the first steps in the conversion of light energy to chemical energy during photosynthesis. The PRC from *Rhodopseudomonas viridis* was the first transmembrane protein with a crystallographically

determined structure that brought the Nobel Prize in Chemistry to Deisenhofer, Huber, and Michel in 1988 (Figure 2b). Two major taxonomic groups of photosynthetic bacteria, purple sulfur bacteria (Chromatiaceae) and purple nonsulfur bacteria (Rhodospirillaceae), contain PRCs of similar structure. PRCs of photosynthetic purple bacteria consist of at least three protein subunits termed L (light), M (medium), and H (heavy); in *R. viridis* and *Thermochromatium tepidum*, the tetraheme (Class IV) cytochrome *c* is the fourth and largest protein subunit. The subunits L and M bind bacteriochlorophylls (BChl), bacteriopheophytins (BPheo), quinones, a ferrous iron ion, and a carotenoid as prosthetic groups. The PRCs from different organisms differ in the types of cofactors used (see Table 5). For instance, PRCs of *Rhodobacter sphaeroides* and *T. tepidum* contain BChl-*a* and BPheo-*a*, while the PRC of *R. viridis* contains BChl-*b* and BPheo-*b*.

8.4. Photosystem II

Photosystem II (PSII) is a multisubunit protein complex spanning the thylakoid membrane of plants, algae, and cyanobacteria that uses light energy to oxidize water to dioxygen:

$$2H_2O \rightarrow O_2 + 4H^+ + 4e^- \quad (3)$$

The light energy is absorbed by chlorophylls and carotenoid pigments of the antenna systems associated with PSII, which vary in different organisms (Barber, 2002). In higher plants, PSII exists as a complex of the "core" with the peripheral light-harvesting complex II (LHCII). PSII assembles as a dimer. Within the PSII core complex, Chl-*a* and β-carotene are bound mainly to the two largest PSII subunits, CP47 (PsbB) and CP43 (PsbC). Chl-*a* and β-carotene absorb the photons and transfer the excitation energy to the reaction center consisting of subunits D1 and D2. The subunits D1 and D2 bind Chl-*a*, Pheo-*a*, quinones, and an iron atom, and are structurally similar to the subunits L and M of the PRC of purple bacteria. The primary electron donor is a "special pair" of Chl-*a* molecules called P680. The O_2 is evolved after removal of four electrons from a catalytic center, comprising a spin-coupled tetramanganese cluster forming a part of the water-oxidizing complex. Apart from the Mn_4 cluster, the water-oxidizing complex contains one Ca^{2+}, one or two Cl^-, and several bridging oxygen ligands (Carrell *et al*., 2002). The Mn_4 cluster is bound at the luminal side of D1.

The crystal structures of cyanobacterial PSII have been solved. It contains the Mn_4 cluster, 36 Chl-*a*, two Pheo-*a*, two hemes, one nonheme Fe, and several β-carotene molecules per monomeric unit (see Table 5). In higher plants and green algae, 25 genes for the PSII core proteins have been identified.

8.5. Photosystem I

Like PSII, PSI is a multisubunit transmembrane protein of the thylakoid membrane. The PSII oxidizes water to O_2, four protons, and four electrons. The electrons are

transferred from PSII to PSI through a pool of plastoquinones, the cytochrome b_6f complex, and a soluble metalloprotein, either the blue copper protein plastocyanin or the Class I cytochrome *c* called cytochrome c_6 (Hervás *et al*., 2003). PSI catalyzes the charge separation across the photosynthetic membrane by transferring the electrons from plastocyanin/cytochrome c_6 to Fe_2S_2 ferredoxin or flavodoxin; finally, the electrons are transferred to the flavoenzyme ferredoxin–$NADP^+$ reductase (EC 1.18.1.2).

PSI combines a PRC with an antenna system. The two largest subunits of PSI, PsaA and PsaB, bind most of the chlorophyll molecules of the antenna system. PSI of higher plants has an additional peripheral light-harvesting complex (LHCI). PSI is the largest membrane protein for which the 3D structure has been solved (*see* Article 99, **Large complexes by X-ray methods**, Volume 6); it also has the largest number of cofactors found in any known protein complex (Figure 2d). The excitation energy is transferred through Chl and the carotenoid molecules to the primary electron donor in the center of the complex. Similar to PSII, the primary electron donor is a Chl-*a* dimer called P700. From P700, a transmembrane electron transfer occurs via a chain of cofactors with descending midpoint potentials (Fromme *et al*., 2003).

The PSI from the cyanobacterium *Synechococcus elongatus* (PDB:1JB0) exists as a trimer with each monomer consisting of 12 protein subunits binding 96 Chl-*a*, 22 β-carotene molecules, three Fe_4S_4 clusters and two phylloquinones. The monomeric PSI from *Pisum sativum* (PDB:1QZV) consists of 12 core subunits and four peripheral subunits (LHCI). It contains 167 Chl-*a* molecules, three Fe_4S_4 clusters and two phylloquinones.

9. Metal storage and transport

9.1. Ferritins

Ferritins are spherical shell-like proteins that play a key role in iron metabolism. Their function is to remove Fe^{2+} ions from solution in the presence of O_2 and to deposit iron into the protein interior in a mineral form. Most known ferritins (InterPro:IPR009040) belong to a large group of diiron–carboxylate proteins. Some bacterial ferritins bind heme; in this case, they are called bacterioferritins (InterPro:IPR002024). The bacterioferritin from *E. coli* (UniProt:P11056) binds heme *b* while the *Desulfovibrio desulfuricans* protein (UniProt:Q93PP9) binds Fe–coproporphyrin III. The tertiary and quaternary structure of ferritins is highly conserved: 24 four-α-helix bundle subunits are arranged as a hollow, symmetrical shell with outside and inside diameters about 125 and 80 Å, respectively (Figure 2e). Up to 4500 iron atoms can be stored in its central cavity as a hydrated iron(III) oxide mineral: mainly ferrihydrite in animal ferritins and hydrated iron(III) phosphate in bacterial ferritins. Subunits pack tightly together except that at the threefold axes there are narrow channels traversing the shell. The threefold channels are the sites of iron transfer into the cavity of the ferritins.

Steps in iron storage within ferritin molecules consist of (1) Fe^{2+} oxidation, (2) Fe^{3+} migration and the nucleation, and (3) growth of the iron core mineral (Harrison and Arosio, 1996). The first step can be represented as

$$Fe^{2+} + O_2 + H_2O \rightarrow Fe^{3+} + H_2O_2 \quad (4)$$

and ferritin can be considered an enzyme catalyzing this reaction.

Another class of ferritins is represented by the dodecameric ferritin from *Listeria innocua* (PDB:1QGH; Figure 2f). This protein contains about 100 iron atoms per dodecamer; it is extremely stable in comparison to the classic 24-meric ferritins and preserves its quaternary structure at a pH as low as 2.0 (Chiaraluce *et al*., 2000).

9.2. Metallochaperones

Metallochaperones are cytosolic metal-binding proteins responsible for the intracellular trafficking of metal ions.

Three types of copper chaperones have been found (Markossian and Kurganov, 2003):

1. Atx1-like copper chaperones bind Cu^+ and interact directly with the Cu-exporting ATPase (EC 3.6.3.4); this family includes the yeast protein Atx1 (UniProt:P38636), its human homolog Hah1 (UniProt:O00244), and CopZ proteins from *Enterococcus hirae* (PDB:1CPZ) and *B. subtilis* (PDB:1K0V).
2. The copper chaperone for SOD (CCS; UniProt:O14618) delivers Cu^+ to Cu,Zn-SOD. This protein consists of three structural domains; the N-terminal domain I is homologous to Atx1, the central domain II is homologous to Cu,Zn-SOD, and the short C-terminal domain III is unique for CCS, which is crucial for copper insertion into apo-SOD.
3. Cox17 (InterPro:IPR007745), Cox11 (InterPro:IPR007533), and Sco1/Sco2 (InterPro:IPR003782) proteins are the copper chaperones for the cytochrome *c* oxidase (COX; EC 1.9.3.1). Cox17 is a soluble protein while Cox11 and Sco1 are located in the mitochondrial inner membrane. Cox17 and Sco1 are thought to provide copper exclusively to the dinuclear Cu_A site of the COX subunit 2 and Cox11 is implicated in the assembly of the mononuclear Cu_B site of the COX subunit 1.

Metallochaperones specific for other metals/metalloprotein targets are known. They include the nickel-binding urease accessory protein UreE (InterPro: IPR007864); the zinc transport protein ZntA (UniProt:P37617); the iron–sulfur cluster assembly proteins NifU and IscU (InterPro:IPR002871); the NafY protein facilitating the transfer of FeMoco to the aponitrogenase (PDB:1P90); and the heme chaperone CcmE required for cytochrome *c* biogenesis (UniProt:P33928).

9.3. Metallothioneins

Metallothioneins (MTs) are a ubiquitous class of diamagnetic low-molecular-weight proteins containing metal–thiolate clusters (Romero-Isart and Vašák, 2002). Various functions such as metal transport, storage, and detoxification have been proposed for MTs; however, the precise role of MTs remains to be established. MTs vary in length, tissue distribution, and metal specificity. Fungal MTs bind Cu^+ while MTs purified from mammals contain Cu, Zn, and Cd.

The 3D structure of the apoprotein (thionein) is mostly disordered. However, animal holo-MTs show a characteristic fold consisting of two globular domains, each binding a metal cluster.

A typical vertebrate MT such as the *Notothenia coriiceps* MT has three metal atoms bound by nine cysteine thiolates in the N-terminal β-domain (PDB:1M0J; Figure 1j), and four metal atoms bound by 11 cysteines in the C-terminal α-domain (PDB:1M0G). This pattern is reversed in an MT from the sea urchin *Strongylocentrotus purpuratus*, which has $Cd_4(S^{\gamma}{}_{Cys})_{11}$ in the N-terminal α-domain (PDB:1QJK) and $Cd_3(S^{\gamma}{}_{Cys})_9$ cluster in the C-terminal β-domain (PDB:1QJK). Crustacean MTs contain two domains, each binding a $Cd_3(S^{\gamma}{}_{Cys})_9$ cluster (UniProt:P29499, UniProt:P55949).

Although only a few residues shorter than the crustacean protein, the yeast MT (PDB:1AQR) binds seven Cu^+ ions in a *single* $Cu_7(S^{\gamma}{}_{Cys})_{10}$ cluster (Figure 1k).

Finally, the protein SmtA from *Synechococcus* sp. (PDB:1JJD) contains the single $Zn_4(S^{\gamma}{}_{Cys})_9(N^{\varepsilon}{}_{His})_2$ cluster (Figure 1l).

10. Conclusion

Metalloproteins have existed as long as protein-based life. Not only are metalloproteins involved in all physiological processes, they affect the whole biosphere. Their spectacular diversity has been demonstrated by structural studies; they nevertheless deserve much more attention from the bioinformatics and proteomics communities.

Specialist Review

Peptidases, families, and clans

Neil D. Rawlings and Alan J. Barrett
Wellcome Trust Sanger Institute, Cambridge, UK

1. Introduction

Peptidases are the enzymes that hydrolyze peptide bonds. The terms "proteolytic enzyme", "protease" and "proteinase" are roughly synonymous with peptidase, but they are redundant, and less satisfactory in several respects, so we deprecate their use. About 2% of genes encode peptidases in all kinds of organisms, and this equates to over 500 active human peptidases. These enzymes catalyze innumerable important biological processes. Posttranslational proteolysis is crucial in the biosynthesis of many proteins, whether it is removal of the methionine that initiates translation of mRNA, of an N-terminal signal or targeting peptide, or of an activation peptide that unmasks the latent activity of an enzyme, protein hormone, or receptor. Physiological processes that depend upon the activities of peptidases include blood coagulation, complement activation, apoptosis, intracellular protein turnover, activation and catabolism of bioactive peptides, tissue remodeling, and the digestion of food. But proteolysis by the endogenous human peptidases is also involved in diseases such as metastatic invasion by cancer cells, Alzheimer's disease, emphysema, and rheumatoid arthritis. The peptidases of foreign organisms contribute to human diseases such as those caused by viruses (e.g., human immunodeficiency virus, poliovirus, influenza virus), bacteria (e.g., *Pseudomonas aeruginosa*, *Clostridium botulinum*, *Bacillus anthracis*), fungi (*Candida*), and protozoa (*Trypanosoma*, *Leishmania*, *Entamoeba*). It is therefore natural that peptidases represent one of the principle drug targets of the pharmaceutical industry.

Because of their large number and importance to human health, peptidases require a major information resource, and the MEROPS database seeks to fill this role. Any database requires the best possible classification and nomenclature for the objects it deals with, and it is the classification of peptidases described herein that is used in the MEROPS database. Also, as necessary, the system is modified and developed in the MEROPS database, so it is sometimes referred to as the MEROPS system, although it can perfectly well stand alone.

The modern system for the classification of peptidases is based on proposals we made in 1993, but before describing that it is appropriate to mention two earlier systems that are still of value. Hartley (1960) made a major contribution to the classification of peptidases by recognizing four types that we now know as serine peptidases, cysteine peptidases, aspartic peptidases, and metallopeptidases. More

recently, two additional catalytic types have been recognized: threonine peptidases (Seemüller *et al*., 1995) and glutamic peptidases (Fujinaga *et al*., 2004). A few peptidases are still of unknown catalytic type.

The second system that must be mentioned is that of the Enzyme Nomenclature of the International Union of Biochemistry and Molecular Biology (Tipton and Boyce, 2000). This strives to be a comprehensive system in which all enzymes are classified on the basis of knowledge of the reactions they catalyze. It is entirely logical that enzymes be classified in terms of their properties as catalysts, and it is important that the Enzyme Nomenclature continues to be maintained and expanded. However, while the IUBMB system is necessary, it is not sufficient for the classification of peptidases in the genomic era. One reason is that an enzyme can be added to the system only when it has been thoroughly characterized enzymologically, which remains a slow process. This is particularly the case for peptidases, which have substrate specificities that are so complex that they are very difficult to define and describe. A second consideration is that classification based on known enzymological activity does not have predictive value for the properties of an enzyme when it is known only as a nucleotide sequence found in a genome. The MEROPS system complements the IUBMB Enzyme Nomenclature with an orthogonal classification of peptidases that is based on homology (as defined by Reeck *et al*., 1987), and reflects the similarities in molecular structure and biology that stem from the evolutionary relationships.

The modern system for classification of peptidases was introduced by the present authors (Rawlings and Barrett, 1993) and has been further developed since then. It is a hierarchical system in which individual peptidases are recognized and then grouped in families. The families are assembled in clans. Some families have subfamilies, and some clans have subclans. Figure 1 illustrates the different levels of the classification, with the example of the large clan PA. Specific issues that arise at each level of the classification are discussed below.

2. Working with individual peptidases

The lowest level of the classification is that of the individual peptidases. The classification is designed for a particular functional group of proteins, those that catalyze the hydrolysis of peptide bonds and their homologs, and as part of their curation of the MEROPS database the present authors have the responsibility of deciding when a novel peptidase needs to be recognized.

Factors tending to support a decision to create a new peptidase identifier include:

- The availability of amino acid sequence data.
- The existence of enzymological data showing that the peptidase activity is unlike that of any peptidase already in the family or subfamily.
- Evidence that the peptidase is the product of a human or mouse gene that is not already in MEROPS. Human and mouse are favored species in that we consider that every peptidase and homolog encoded by their genomes merits a separate identifier in MEROPS. We plan to add additional species to the list in the future.

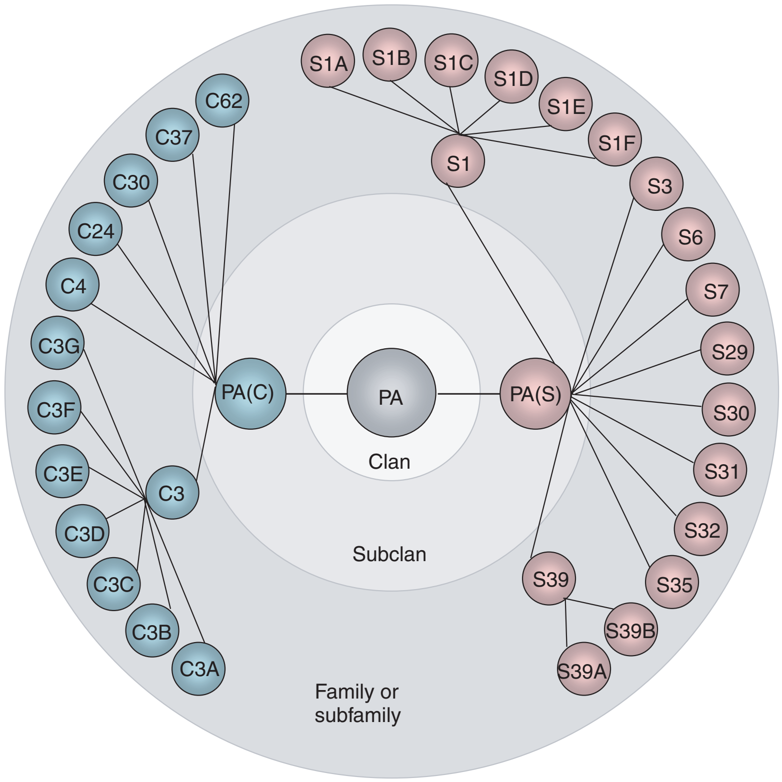

Figure 1 The hierarchical classification, from subfamily to clan. Clan PA contains both cysteine peptidases and serine peptidases, the relationship of which is detectable by strikingly similar protein folds. The letter "P" is used in forming the identifier of the clan because it contains the two types of protein nucleophile peptidases. Subclans PA(C) and PA(S) accommodate the families of cysteine peptidases and serine peptidases respectively. Some families contain subfamilies, numbering as many as seven in family C3; these are handled similarly to simple families

- Available biological data show that the peptidase has a distinctive function or distinctive spatial or temporal distribution in the organism.

Although not a requirement, it does speed up the process of recognition of a new peptidase entity if a good name has been proposed for it. If we are uncertain whether to create a new peptidase entity, we take a view as to whether it will be useful to the scientific community if we do so.

An identifier is assigned to each novel peptidase. This consists of a three-character form of the family name (see below), a dot and a three-digit serial number. If the peptidase cannot be placed in an existing family, a new family is created. Many peptidases have not yet been characterized to the extent that they can be assigned to precise identifiers, and these are provisionally described only as unassigned peptidases in the family or subfamily.

Once a new identifier has been created, we need to consider whether additional homologs are known that are close enough in sequence to merit assignment to

the same identifier, even without biochemical characterization. Typically, these appear to be variants of the same peptidase from other species. We maintain a sequence alignment and a similarity tree for each family and subfamily, and these make it simple to see sequences that cluster together. We may well assign the same MEROPS identifier to the entire cluster. Sequence alignments are made by using the programs MAFFT (Katoh *et al*., 2002) and ClustalW (Thompson *et al*., 1994), and trees are made with either the UPGMA algorithm as implemented in the QUICKTREE program (Howe *et al*., 2002) or the KITSCH algorithm from the PHYLIP package (Felsenstein, 1989). Ideally, only one sequence from an organism is assigned to a given identifier, but, in practice, lineage-specific expansion may have given rise to several close paralogs within a single species, any of which could be assigned to the identifier. Unless we have biochemical evidence to the contrary, all such sequences tend to be assigned to the same identifier. We are reluctant to assign sequences that differ by more than 50% of amino acid residues to the same identifier except in the light of evidence that other properties are similar, because the probability is that key characteristics will have changed at this level of divergence.

An example of the usefulness of similarity trees in distinguishing individual peptidases is provided in Figure 2. This is a tree for just the human and mouse members of family A1. Renin 2 has resulted from a recent duplication of the renin gene in mouse, and human pepsin A and mouse pepsin F, although encoded by orthologous genes (Puente *et al*., 2003), are too divergent to be considered the same peptidase. The decision to give pepsins A and F separate identifiers is supported by experimental evidence of differences in the activity and expression of the enzymes (Chen *et al*., 2001).

Properties that are recorded for every peptidase that has an identifier are (1) the identity of the *holotype* of the enzyme, (2) the accession number for the *type sequence*, (3) the extent of the *peptidase unit*, and (4) the positions of *active site* (catalytic and metal ligand) residues in the sequence.

We assume that every peptidase is encoded by the genomes of multiple organisms so that species variants exist that can be expected to show minor variations in properties. In order to be able to describe the properties of the peptidase with precision, we need a reference species variant. An example of such a definition is that for identifier M10.008 the *holotype* of which is “matrilysin (*Homo sapiens*)”.

Commonly, there are several deposits of sequences for a single peptidase that have minor differences as a result of sequencing errors, inclusion or exclusion of the initiating methionine, or genetic polymorphisms. In the interests of precision, we define a type sequence with a particular accession number for each peptidase. To continue with the example of matrilysin, this is “matrilysin (*Homo sapiens*), Uniprot Accession P09237”.

Many peptidases are multidomain proteins in which one can recognize a part of the molecule that carries the active site residues and is responsible for peptidase activity (termed the *peptidase unit*) as distinct from parts that may have other functions (Figure 3). Often, the peptidase unit is equivalent to the entire, mature sequence of the smallest active peptidase in the family. Figure 3 shows how the peptidase units have been defined for the peptidases related to collagenase 1 in family M10. The shortest sequence is that of matrilysin, and since this is an active

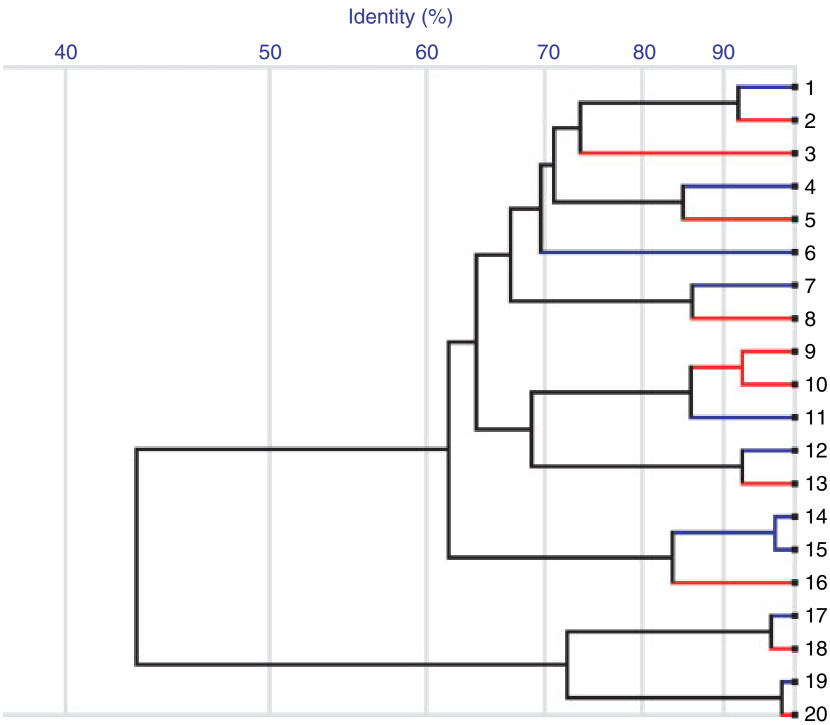

Figure 2 Distinct human and mouse peptidases resolved with the use of a sequence-similarity tree for family A1 of pepsin. The tree was made with only human and mouse sequences for simplicity. The ultimate branch is shown in blue for a mouse sequence, and red for human. Numbers across the top are percentage identity. Key to sequences (MEROPS identifier, species, protein name, UniProt accession, peptidase unit): (1) A01.010 (*Mus musculus*) cathepsin E (P70269) (residues: 69-394); (2) A01.010 (*Homo sapiens*) cathepsin E (P14091) (residues: 67-393); (3) A01.001 (*H. sapiens*) pepsin A (P00790) (residues: 63-388); (4) A01.006 (*M. musculus*) chymosin (-) (residues: 61-376); (5) A01.006 (*H. sapiens*) chymosin (-) (residues: 68-433); (6) A01.051 (*M. musculus*) pepsin F (Q9JKE6) (residues: 61-385); (7) A01.003 (*M. musculus*) gastricsin (-) (residues: 67-389); (8) A01.003 (*H. sapiens*) gastricsin (P20142) (residues: 61-388); (9) A01.972 (*H. sapiens*) napsin B pseudogene (napsin B pseudogene) (Q9UHB3) (residues: 69-393); (10) A01.046 (*H. sapiens*) napsin A (human-type) (O96009) (residues: 69-399); (11) A01.049 (*M. musculus*) napsin A (mouse-type) (O09043) (residues: 63-387); (12) A01.009 (*M. musculus*) cathepsin D (P18242) (residues: 71-405); (13) A01.009 (*H. sapiens*) cathepsin D (P07339) (residues: 71-410); (14) A01.007 (*M. musculus*) renin (P06281) (residues: 76-399); (15) A01.008 (*M. musculus*) renin-2 (P00796) (residues: 75-398); (16) A01.007 (*H. sapiens*) renin (P00797) (residues: 78-403); (17) A01.041 (*M. musculus*) memapsin-1 (Q9R1P7) (residues: 90-425); (18) A01.041 (*H. sapiens*) memapsin-1 (Q9Y5Z0) (residues: 93-428); (19) A01.004 (*M. musculus*) memapsin-2 (P56818) (residues: 77-416); (20) A01.004 (*H. sapiens*) memapsin-2 (P56817) (residues: 77-416)

peptidase we take the parts of the sequences of the other members of the family that align with the mature matrilysin sequence as their peptidase units. Matrilysin provides an example of the typical, simple style of definition of a peptidase unit: “matrilysin (*Homo sapiens*), Uniprot Accession P09237 (peptidase unit: 93-267)”. The two gelatinases in family M10 are more complex, in that they have domains

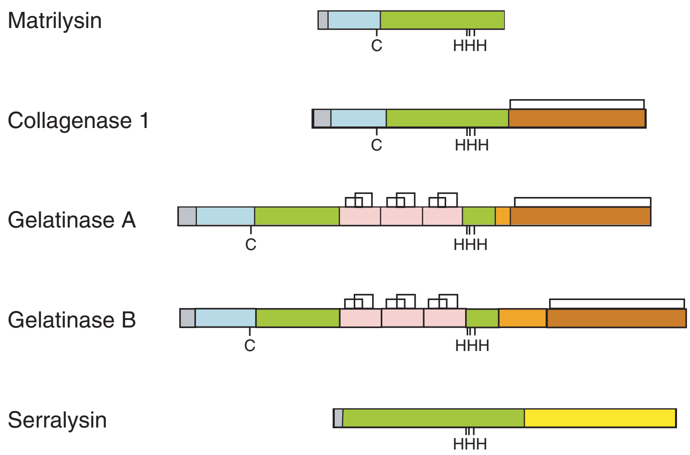

Figure 3 Peptidase units in family M10. The domain organizations of several members of peptidase family M10 are shown. The peptidase units are colored in green. The domains excluded from the peptidase units are signal peptides (gray), propeptides (blue), hemolysin-like domains (brown), fibronectin-like repeats (pink), and a calcium-dependent secretion domain (yellow). The positions of disulfide bridges are marked, as are the cysteine residues of the "cysteine switches" that maintain the latency of the proenzymes, and the zinc-binding histidine residues of the active sites

nested within the peptidase unit, and the special case of the interrupted peptidase unit is dealt with as: "gelatinase A (*Homo sapiens*), Uniprot Accession P08253 (peptidase unit: 108-214, 390-461)". Amino acid residue numbers can only be specified in the context of a particular version of the amino acid sequence, and the Uniprot accessions indicated here are termed the "type sequences" for the MEROPS identifiers M10.008 and M10.003, respectively. It is the sequence of each peptidase unit rather than that of the whole protein that is aligned and used in constructing trees for MEROPS. The Pfam (*see* Article 86, **Pfam: the protein families database**, Volume 6) and SMART databases (Letunic *et al*., 2004) manage protein domains in similar ways to peptidase units in MEROPS.

Data for the positions of catalytic residues in each peptidase sequence allow a check that any additional sequence that is assigned to the same identifier is that of a protein that has at least the potential to be catalytically active.

Since the classification of peptidases is strictly a classification of peptidase units, a problem arises when a single peptidase molecule contains more than one peptidase unit: no single location in the classification is right for the whole of such a compound peptidase molecule. To deal with the half-dozen or so of such cases, a special type of peptidase identifier starting in "X" exists for each compound peptidase, and an identifier of the standard type is used for each of the individual peptidase units. For example, the somatic form of peptidyl-dipeptidase A (angiotensin-converting enzyme), which contains two homologous peptidase units (M02.001 and M02.004), is XM02-001. In addition to the expected summary pages for M02.001 and M02.004, there is a special summary card for XM02-001.

3. Classification at the family and subfamily levels

We create a new peptidase family when there are data to show that a protein that cannot be placed in an existing family has peptidase activity. In founding a new family, we recognize a type-example peptidase for the family.

Every family contains peptidases of just a single catalytic type, and the catalytic type is a key property of the family that forms the basis of the family identifier. If a novel peptidase is founding a new family, experimental data as to its catalytic type are sought. Typically, amino acid residues that are conserved in all of a homologous set of peptidases will have been mutated experimentally, and effects on activity determined; a conserved residue that is essential for activity may well show the catalytic type. The initial letter of the new family identifier reflects the catalytic type ("A" for aspartic, "C" for cysteine, "G" for glutamic, "M" for metallo, "S" for serine, "T" for threonine, or rarely "U" for unknown), and this is followed by a serial number. A family identifier is permanently deleted if it is subsequently found that none of the proteins in the family is a peptidase after all. The identifier may also be deleted if the family is merged with another family, because the lower-numbered identifier of the two is used for the merged family.

The majority of families of peptidases (139 out of the 180 families in MEROPS Release 6.6) do not contain subfamilies, and these can be described as *simple families*, whereas the 31 families that are divided into subfamilies can be termed *compound families*. The similarity trees for the compound families show sets of sequences that are separated by deep divergences (typically falling to 33% of amino acid sequence identity) (Figure 4). When such a distinct subset contains at least one characterized peptidase, the set is treated as a subfamily. A type peptidase is then nominated for the subfamily and an identifier assigned. The identifier of a subfamily is that of the family with the addition of a serial capital letter (e.g., A22B).

The subfamilies of compound families are handled in just the same way as the simple families, but the compound families require special procedures. A family or subfamily may contain just a single peptidase so long as this has been thoroughly characterized.

Additional members of families are found by searches made with the programs FastA (Pearson and Lipman, 1988), BlastP, and TBlastN (Altschul *et al*., 1990). A sequence is considered to be homologous to the query sequence if the expect value (e) is 0.001 or less. Several types of searches are made:

1. The peptidase unit of the type-example peptidase of each family or subfamily is used as the query sequence in a BlastP search of the UniProt database.
2. Newly deposited sequences of peptidases identified during our weekly literature surveys are used in FastA searches of the library of sequences in the MEROPS database, PepUnit.Lib. If the new sequence is found to be significantly related to a sequence in PepUnit.Lib, but not to the type example of that subfamily, then a *transitive relationship* is considered to exist.
3. Sequences that are linked to a type-example sequence only by transitive relationships form a second set of query sequences that are used in BlastP searches of the UniProt database (Apweiler *et al*., 2004).

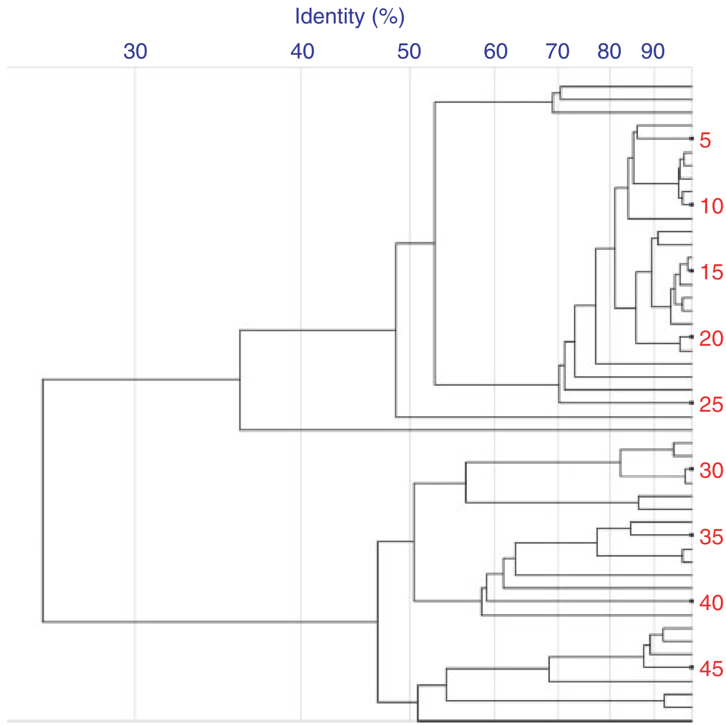

Figure 4 Tree for a compound family of peptidases. The tree for family A22 (from MEROPS Release 6.5) shows the deep divergence to below 30% sequence identity between subfamily A22A (tips 1–27) containing the presenilins and their homologs, and subfamily A22B (tips 28–49) containing signal peptide peptidase and its homologs. The full key to the sequences can be found in the MEROPS database (**http://merops.sanger.ac.uk**)

4. The peptidase unit of the type-example peptidase of each family or subfamily, and of each sequence linked to the type-example sequence only by a transitive relationship, serves as the query sequence in a TBlastN search of the EMBL nucleotide sequence database (Kulikova *et al*., 2004).
5. The peptidase unit of the type-example peptidase of each family or subfamily, and of each sequence linked to the type-example sequence only by a transitive relationship, serves as the query sequence in a FastA search against every newly completed genome sequence deposited at the DDBJ/EMBL/Genbank nucleotide sequence databases.

From time to time, a sequence is encountered that serves as a *linking sequence* between two families. This is a sequence that can be shown to be homologous to one or more members from each family. Rarely, a linking sequence is found in a BlastP or FastA search. More often, the BlastP or FastA results file includes members of another family that are above our expect value threshold. If this happens frequently, it may be that the two families should be merged. We then search for

linking sequences by use of shuffling tests made with the program PRSS34 from the FastA package (Pearson and Lipman, 1988).

4. Classification at the clan and subclan levels

A clan is intended to contain the full set of modern-day peptidases that have arisen from a single ancestral peptidase. These are commonly much more divergent than the peptidases in a single family, so most clans contain several families. The distant relationships at the clan level can sometimes be seen in the order of catalytic residues in the polypeptide chains, or in conserved amino acid sequence motifs around the catalytic residues, but similarities in protein fold provide the strongest justification for grouping families in a clan.

For a clan to be established, the tertiary structure of at least one member of a family must have been solved. Other families may be added to the clan if their peptidases have protein folds that are similar to that of the type peptidase of the clan. The comparison of tertiary structures requires great skill, and we rely upon the views of the authors of papers describing the tertiary structures, the classifications of protein structures by the SCOP (Andreeva *et al*., 2004) and CATH (*see* Article 89, **The CATH domain structure database**, Volume 6) databases, and results obtained from the DALI program (Holm and Sander, 1993).

Peptidase families are grouped in a clan only if the positions of the active site residues (and metal ligands of metallopeptidases) are consistent with common ancestry. There are a number of families that are included in the same SCOP superfamily or are found to be significantly similar by DALI, but for which the active sites are in different positions in the structures. This suggests that the peptidase active sites have evolved independently, although perhaps on homologous protein scaffolds.

The identifier of a clan consists of two letters, the first indicating the catalytic type of all the families in the clan and the second being a serial letter. The initial letter is taken from the set used for family identifiers (A, C, G, M, S, T, U) or may be P, because there are some clans that contain mixtures of protein nucleophile (i.e., C, S, T) families. If deleted, a clan identifier is not reused.

There are families for which no tertiary structure is known and which cannot reliably be assigned to clans. Instead, we assign these families to *pseudoclans* with names A-, C-, M-, S- and U-, depending on catalytic type. Assignment of a family to such a pseudoclan does not imply that its peptidases are related to others in the pseudoclan, but is simply a way of grouping them for practical convenience.

Four clans are divided into *subclans* in MEROPS Release 6.6 (Table 1). Three of these (PA, PB, PC) contain families of mixed protein nucleophile catalytic types. In all of these, the active sites are very similar in structure but the nucleophilic residue has changed. One clan of metallopeptidase also is divided into subclans. This contains the numerous families of peptidases that have the "HEXXH" motif at the active site, and is divided into the gluzincins (subclan MA(E)) and the metzincins (subclan MA(M)) (Hooper, 1994; Bode *et al*., 1993). The name of a

Table 1 Subclans of peptidases. Four clans are divided into subclans in MEROPS Release 6.5, three of them because they contain multiple catalytic types of protein nucleophile peptidases, and the fourth because it contains the different kinds of metallopeptidase families that have been described as gluzincins and metzincins

Clan	Subclan	Explanation of subclan identifier
PA	PA(C)	**C**ysteine-type peptidase
	PA(S)	**S**erine-type peptidase
PB	PB(C)	**C**ysteine-type peptidase
	PB(S)	**S**erine-type peptidase
	PB(T)	**T**hreonine-type peptidase
PC	PC(C)	**C**ysteine-type peptidase
	PC(S)	**S**erine-type peptidase
MA	MA(E)	Glu-zincin (most C-terminal zinc ligand is Glu, **E**)
	MA(M)	Met-zincin (contains the **M**et-turn structure, and the most C-terminal zinc ligand is not Glu)

subclan is formed from the clan name by placing a letter in parentheses at the end; this is not a serial letter, but reflects a characteristic of the active site.

5. The MEROPS database

The classification of peptidases is constantly evolving and expanding to accommodate new data, and the MEROPS database provides the medium through which the successive updates are published. New releases of MEROPS appear on the Internet quarterly, where they are freely accessible to all under general library license (**http://merops.sanger.ac.uk**) (Rawlings *et al.*, 2004a).

The forms of information that are provided in MEROPS can be briefly summarized as follows. For each clan of peptidases, there is a selective sequence alignment showing conservation of amino acids around the active site residues for the type example for each family in the clan. There are also images showing the similarities in secondary structure, and a bibliography. The summary page for the clan shows the type example, the list of families in the clan, and the distribution of peptidases across kingdoms of organisms.

For each family, there is an alignment of the protein sequences of active peptidase units, a tree derived from the alignment, and a figure showing whether a homolog can be found in each of the available whole-genome sequences. There are also images showing the similarities in secondary structure, a bibliography, and collections of human and mouse sequences. The summary lists the type example, links to structure databases such as SCOP (Andreeva *et al.*, 2004), CATH (*see* Article 89, **The CATH domain structure database**, Volume 6), and HSSP (Dodge *et al.*, 1998), databases for domain and family classification such as Pfam (*see* Article 86, **Pfam: the protein families database**, Volume 6), and InterPro (*see* Article 83, **InterPro**, Volume 6), and the PROSITE (*see* Article 84, **Functionally and structurally relevant residues in PROSITE motif descriptors**, Volume 6) database of sequence motifs as well as the HomStrad database of structural alignments (Mizuguchi *et al.*, 1998). There is also a list of peptidases in the family,

and a table of distribution amongst kingdoms of organisms. When a family is divided into subfamilies, these are shown.

At the peptidase level, there is a list of sequence database entries for every organism from which the peptidase is known, as well as a diagram showing the distribution of the peptidase amongst all the species from which any member of the family is known. If tertiary structures have been published, there is a Richardson diagram (Richardson, 1985) of this and a list of PDB entries (Berman *et al*., 2000). Also provided are a bibliography, alignments and tables of known human and mouse expressed sequence tags, and a list of substrates and cleavage sites. The summary shows other names, the full MEROPS classification, comments on pharmaceutical and physiological relevance, and human and mouse genetics.

Access to the data is facilitated by indexes of peptidase names, MEROPS identifiers, and source organisms. There are also CGI and Blast searches.

In Release 6.4, a classification of the proteins that inhibit peptidases was added to the MEROPS database. We found that we could classify the inhibitors by methods similar to those that we had developed for peptidases (Rawlings *et al*., 2004b), and we believe that this demonstrated that a similar approach could be applied to other functionally related groups of proteins.

6. Conclusions

The homology-based system for the classification of peptidases is described. This is well suited to the genomic era because it allows predictions about the functions of novel peptidases while they are known only by sequence. The system has now become established worldwide for identifying peptidase families and provides the structure of the public MEROPS database. The separate set of proteins that act as inhibitors of peptidases was recently classified in the same way, and we believe that this sort of system could be applied to other functional groups of proteins.

Specialist Review

Transporter protein families

Qinghu Ren and Ian T. Paulsen
The Institute for Genomic Research, Rockville, MD, USA

The cellular membrane is a selectively permeable barrier between the cell and the extracellular environment. The movement of molecules and ions across cellular membrane is mediated by selective membrane transporters embedded in the phospholipid bilayer. Transporters function in the acquisition of organic nutrients, extrusion of toxic and waste compounds, maintenance of ion homeostasis, environmental sensing and cell communication, and other important cellular functions (Saier, 1999a). The complement of transporter systems displays great variations in different species (Figure 1). Between 2 and 16% of open reading frames (ORFs) in the prokaryotic and eukaryotic genomes are predicted to encode membrane transport proteins, emphasizing the important roles of transporters in the lifestyles of all species (Paulsen *et al*., 2000).

Various transport systems differ in their putative membrane topology, energy-coupling mechanism, and substrate specificities (Saier, 2000). The most common energy-coupling mechanisms are the utilization of adenosine triphosphate (ATP), phosphoenolpyruvate (PEP), or chemiosmotic energy in the forms of sodium ion or proton electrochemical gradients. Transporters of similar functions characteristically cluster together in phylogenetic analyses, hence substrate specificity appears to be a conserved evolutionary trait in transporters, and phylogeny can provide a rational basis for functional assignment (Paulsen *et al*., 2000; Paulsen *et al*., 1998b). The Transporter Classification (TC) system (**http://saier-144-164.ucsd.edu/tcdb/**) represents a systematic approach to classify membrane transporter families according to the mode of transport, energy-coupling mechanism, molecular phylogeny, and substrate specificity (Busch and Saier, 2004; Saier, 1999). The TC system is analogous to the Enzyme Commission (EC) system for classification of enzymes, except that it incorporates both functional and phylogenetic information. Transport mode and energy-coupling mechanism serve as the primary base for the classification owing to their relatively stable characteristics. There are four characterized classes of solute transporters in the TC system: channels, secondary transporters, primary active transporters, and group translocators (Figure 2). Transporters of unknown mechanism or function are included as a distinct class.

- *Class 1. Channels/pores:* Channels are energy-independent transporters that transport water, specific types of ions, or hydrophilic small molecules down a concentration or electric gradient with higher rates of transport and lower

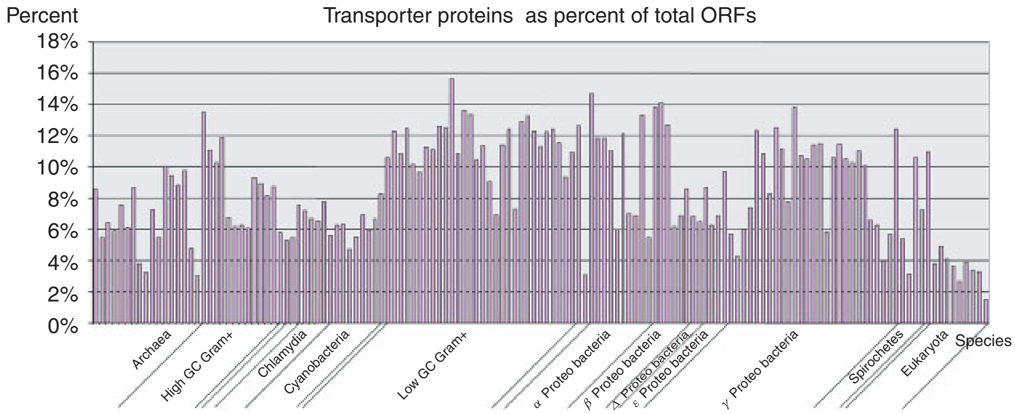

Figure 1 A comparison of the overall numbers of recognized transporter proteins relative to the total ORF numbers for the 141 species analyzed in the TransportDB database

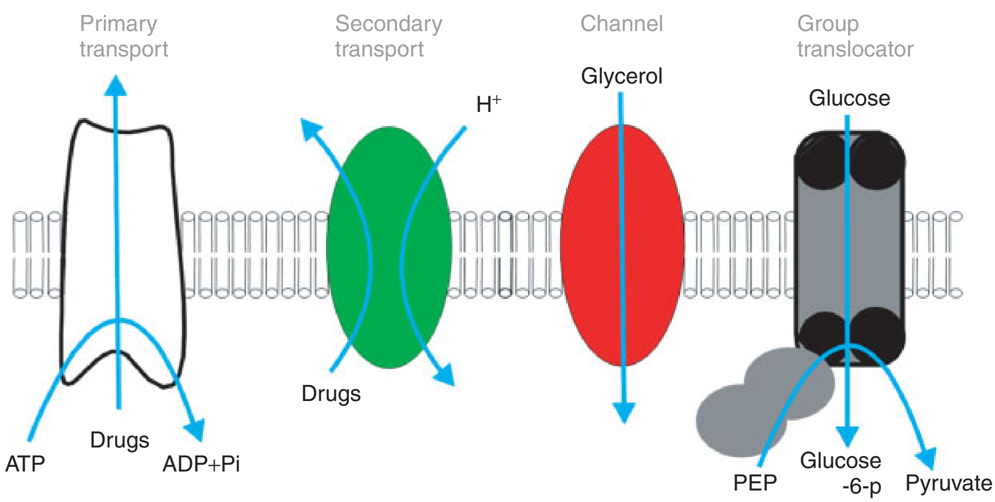

Figure 2 Representative examples of the four main types of transporters. Primary transporter, *Lactococcus lactis* LmrP multidrug efflux pump (Bolhuis *et al*., 1995); secondary transporter, *Staphylococcus aureus* QacA multidrug efflux transporter (Tennent *et al*., 1989); channel, *Escherichia coli* GlpF glycerol channel (Sweet *et al*., 1990); and group translocator, *E. coli* PtsG/Crr glucose PTS transporter (Henderson *et al*., 1977)

stereospecificity compared to other transporter classes. Most of the ion channels, referred to as *gated channels*, open only in response to specific chemical or electric signals.

- *Class 2. Electrochemical potential-driven transporters (secondary transporters):* Secondary transporters (also called carriers) utilize an ion or solute electrochemical gradient, for example, proton/sodium motive force, to drive the transport process. Uniporters move a single type of molecule down its concentration gradient. Antiporters and symporters couple the transport of ions or molecules against

their concentration gradient with the movement of one or more different ions or molecules down their gradient.

- *Class 3. Primary active transporters:* Primary active transporters couple transport process to a primary source of energy, such as a chemical reaction (e.g., ATP hydrolysis), and move substrates across membrane against a chemical concentration gradient or electric potential or both.
- *Class 4. Group translocators:* Group translocators modify their substrates during the transport process. For example, the bacterial phosphotransferase system (PTS) phosphorylates its sugar substrates using phosphoenolpyruvate as the phosphoryl donor and energy source and releases them into cytoplasm as sugar phosphates.
- *Class 9. Incompletely characterized transporter systems:* Transporter protein families for which insufficient information is available to allow classification in a defined class belong to this class.

Each transporter class is further classified into individual families or superfamilies according to their function, phylogeny, and/or substrate specificity (Saier, 2000). A specific transport protein can be represented by a TC number, which normally has five components as follows: V.W.X.Y.Z. V (a number) corresponds to the transporter type (i.e., channel, secondary transporters, primary active transporters, or group translocators); W (a letter) corresponds to the transporter subtype, which in the case of primary active transporters refers to the energy source used to drive transport; X (a number) corresponds to the transporter family; Y (a number) corresponds to the subfamily in which a transporter is found; and Z corresponds to the substrate or range of substrates transported. For example, the well-characterized *Escherichia coli* LacY lactose permease (Kaback *et al*., 2001) is represented in the TC system as 2.A.1.5.1, where "2" indicates it is a secondary transporter, "A" indicates it is a uniporter/symporter/antiporter, "1" indicates it belongs to the Major Facilitator Superfamily (MFS), "5" indicates it belongs to an oligosaccharide symporter subfamily within the MFS family, and "1" indicates it is a lactose/proton symporter. Transport system families included in the current TC system are available in database format on the web (TCDB, **http://saier-144-164.ucsd.edu/tcdb/**). TCDB provides detailed information and references for each transporter class, subclass, family, subfamily, and individual proteins. The website also provides a search tool that allows users to search by keyword, gene name, family, or protein sequence (Busch and Saier, 2004).

Membrane transport proteins typically consist of multiple transmembrane α-helical segments (*see* Article 38, **Transmembrane topology prediction**, Volume 7). The hydrophobic nature and solubility only in presence of detergents make them difficult to study experimentally (*see* Article 65, **Analysis and prediction of membrane protein structure**, Volume 7). Genomic and bioinformatics analyses provide an attractive alternative. More than 180 prokaryotic and eukaryotic genomes have been published to date, with over 900 additional genome-sequencing projects currently underway around the world. An in-depth look at transport proteins is vital to the understanding of the metabolic capability of organisms. We have previously undertaken systematically genome-wide comparisons of the transporter systems and families across a wide range of sequenced organisms (Paulsen *et al*., 2000; Paulsen *et al*., 1998b), and similar studies have been done on specific

genomes (Meidanis *et al*., 2002; Paulsen *et al*., 1998a). Convenient and effective bioinformatics methods for whole-genome transporter analysis have been developed (Ren *et al*., 2004). TransportDB (**http://www.membranetransport.org/**) is a relational database describing the predicted cytoplasmic membrane transport protein complement for organisms whose complete genome sequences are available. For each organism, its complete membrane transport complement was identified, classified into protein families according to the TC classification system, and functional predictions are provided. The web pages also include various features such as a search engine, a BLAST search tool, a comparative genomics page, and phylogenetic information of individual transporter families. Currently, TransportDB contains data from 141 species, including 115 bacteria, 17 archaea, and 9 eukaryotes. Transporter proteins from these organisms were identified and classified into 134 families, including 7 families of primary transporters, 80 families of secondary transporters, 32 channel protein families, 2 phosphotransferase systems, and 13 unclassified families. Some of these families are very large superfamilies with numerous members, such as the ATP-binding Cassette (ABC) Superfamily and the MFS, both of which are widely distributed in bacteria, archaea, and eukaryotes (Table 1). Some are very small families with only few members present in certain species.

The occurrence of transporter families in the three domains of life (*see* Article 40, **The domains of life and their evolutionary implications**, Volume 7) is shown in Figure 3. There are 41 eukaryotic-specific families, mainly the channel families in class 1, which exist exclusively in multicellular eukaryotic species such

Table 1 The top 10 largest transporter families in the TransportDB database. Most of them are widely distributed in bacteria, archaea, and eukaryotic species, with the exception of SSPTS (bacteria) and MC (eukaryotes)

Family ID	Family name	TC#	Count[a]	Occurrence[b]
ABC	The ATP-binding Cassette (ABC) Superfamily	3.A.1	913	B, A, E
MFS	The Major Facilitator Superfamily (MFS)	2.A.1	819	B, A, E
DMT	The Drug/Metabolite Transporter (DMT) Superfamily	2.A.7	511	B, A, E
RND	The Resistance-Nodulation-Cell Division (RND) Superfamily	2.A.6	433	B, A, E
SSPTS	Sugar Specific Phosphotransferase System	4.A	415	B
APC	The Amino Acid-Polyamine-Organocation (APC) Family	2.A.3	408	B, A, E
MOP	The Multidrug/Oligosaccharidyl-lipid/Polysaccharide (MOP) Flippase Superfamily	2.A.66	405	B, A, E
VIC	The Voltage-gated Ion Channel (VIC) Superfamily	1.A.1	394	B, A, E
P-ATPase	The P-type ATPase (P-ATPase) Superfamily	3.A.3	384	B, A, E
MC	The Mitochondrial Carrier (MC) Family	2.A.29	242	E

[a]Transporter count in 141 species analyzed
[b]B: bacteria; A: archaea; E: eukaryotes.

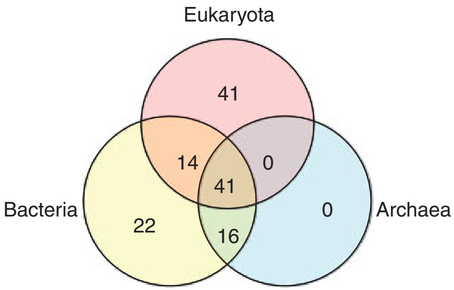

Figure 3 Distribution of transporter families among three domains of life. A total of 134 families have been identified, including 41 eukaryotes-specific families, mainly the various ion channels, which exist exclusively in higher eukaryotic species, and 38 prokaryotes-specific families, of which 22 families only exist in bacteria and 16 are shared by bacteria and archaea. About 41 families are shared by both prokaryotic and eukaryotic species

as *Drosophila melanogaster*, *Arabidopsis thaliana*, and humans, and usually are restricted to a single organismal type. Prokaryotic-specific transporter families (38 families), of which 22 families only exist in bacteria and 16 are shared by bacteria and archaea, are more prevalent than those specifically found in eukaryotes, possibly reflecting that prokaryotes endure more evolutionary pressure, which force them to maintain diversity so that they could be adaptive in response to the various environmental stress conditions. There are no archaea-specific transporter families known, partly reflecting the sparse functional characterization of archaeal proteins. About 41 families are ubiquitous in all three domains of life, highlighting the fundamental importance of these families. Most of them are found within subclass 2A. There are 14 families shared by bacteria and eukaryotes and 16 shared by bacteria and archaea. Some of these families shared only in two domains could be ubiquitous with more sequence data available for analysis.

In general, eukaryotic species, especially multicellular eukaryotic organisms, such as *Drosophila* (640 transporters), *Arabidopsis* (855 transporters), *Caenorhabditis elegans* (656 transporters), and humans (805 transporters), exhibit much larger numbers of total transporter proteins than prokaryotic and lower eukaryotic systems, but the transporter proteins in eukaryotes occupy a smaller percent of total ORFs (average 3.3%) compared to those in prokaryotic systems (average 5.4%) (Figure 1). Although multicellular eukaryotes exhibit fewer transporter families than prokaryotes, they have generated an extraordinary number of paralogs by gene duplication or expansion within certain families, such as ABC, MFS, and the Voltage-gated Ion Channel (VIC) Superfamily, probably evolved into tissue-specific and/or organelle-specific functions. Species with intracellular lifestyles, including intracellular prokaryotic pathogens such as *Mycoplasma* spp. and *Chlamydia* spp., symbionts such as *Buchnera* sp., *Wolbachia* sp., and *Wigglesworthia brevipalpis*, and eukaryotic parasites such as *Plasmodium falciparum* and *Encephalitozoon cuniculi*, usually exhibit a more limited repertoire of membrane transporters. Most of the sequenced archaea are also underrepresented in transporters relative to the total ORFs, in some cases because of their largely autotropic metabolism, or possibly

because of more limited experimental characterization of these organisms. Soil-/plant-associated organisms, such as *Mesorhizobium loti*, *Sinorhizobium meliloti*, *Agrobacterium tumefaciens*, *Bradyrhizobium japonicum*, *Pseudomonas aeruginosa*, and *Bacillus subtilis*, all of which have a free-living lifestyle, possess a robust array of transporter systems (Paulsen *et al*., 2004). The prevalent number of transporter families and total transporter proteins are consistent with the evolution of adaptive responses to changes in environment, which permits these organisms to thrive in diverse ecological niches.

Phylogenetic analyses of membrane transporters can be used to examine in detail specific subtypes or subfamilies across all the sequenced genomes. Previous studies have shown that substrate specificity is a highly conserved evolutionary trait and that transporters with similar substrate specificities tend to cluster together (Chang *et al*., 2004; Paulsen *et al*., 2000; Saier, 1996; Saier *et al*., 1999b). An example of this phenomenon is demonstrated in the phylogenetic tree of human ABC transporters displayed in Figure 4. The ABC transporter superfamily is one of the largest families

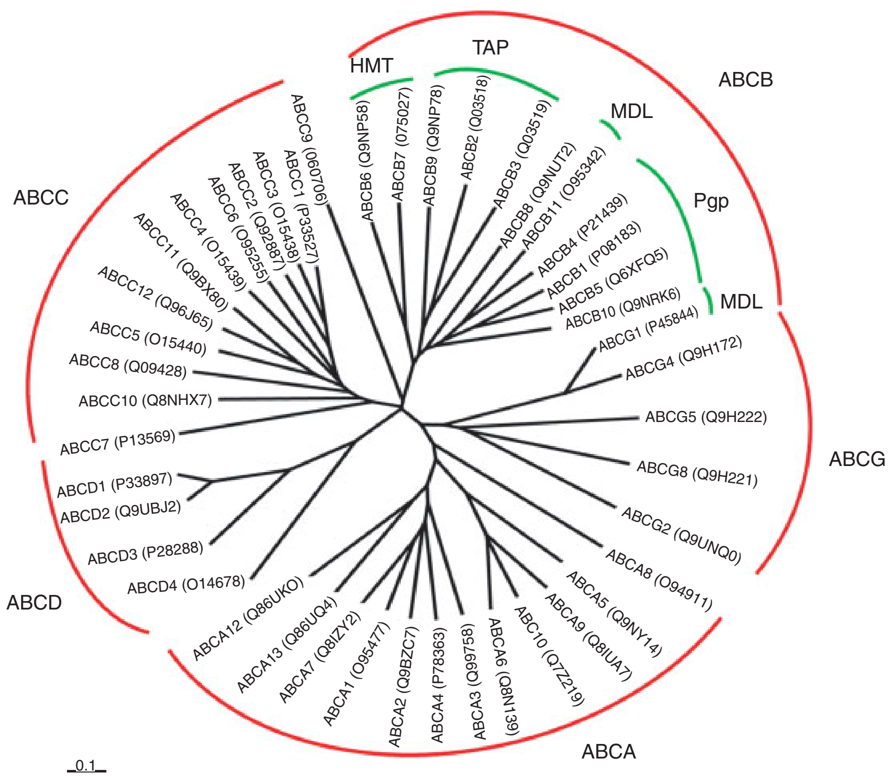

Figure 4 Unrooted phylogenetic tree of human ABC transporters. UniProt accession numbers are used to represent proteins. Five major subfamilies are labeled. The ABCB subfamily can be further classified into smaller groups with similar functions. Predicted ABC transporters are aligned to the Pfam model (*see* Article 86, **Pfam: the protein families database**, Volume 6) ABC_tran (accession PF00005). The Neighbor-joint tree was constructed using CLUSTALX (Thompson *et al*., 1997)

in the genomes of both prokaryotes and eukaryotes, with thousands of identified members. Most ABC transporters consist of four structural domains: two very hydrophobic transmembrane (TM) domains, which contain six membrane-spanning α-helices and two hydrophilic cytoplasmic ATP-binding domains, which transfer the energy for the transport process. ABC transporters are involved in the import or the export of a diverse substrate spectrum, including drugs, inorganic anions and cations, lipids, amino acids and peptides, sugars, carboxylates, and so on. ABC importers typically require an additional substrate-binding protein and are prokaryotic-specific. Prokaryotic ABC transport systems usually carry TM and ABC domains encoded by separate genes that are often organized in gene operon or cluster. ABC exporters are found in both prokaryotic and eukaryotic species, which are involved in the extrusion of waste, drugs, and extracellular toxins. The TM and ABC domains are usually fused in different combinations (Dean and Allikmets, 2001).

The whole-genome analysis of human transporters indicated that the human genome encodes 44 putative ABC transporters. Phylogenetic tree analyses were conducted on the ATP-binding domain of these transporters (Figure 4). Five major subfamilies can be identified with different functions and/or substrate specificities:

- The ABCA subfamily comprises 12 human transporters. The ABCA subfamily proteins are highly conserved in mammals and are present in *Drosophila*, *Arabidopsis*, *C. elegans*, *Anopheles gambiae*, *Dictyostelium discoideum*, *Cyanidioschyzon merolae*, and *Aspergillus fumigatus*, but are absent from yeast and intracellular parasites like *Cryptosporidium parvum*, *P. falciparum*, and *E. cuniculi* (Table 2), suggesting that ABCA family genes have been lost during evolution from the majority of the fungi and lower eukaryotic lineage. These transporters can be further divided into two distinct clusters on the basis of phylogenetic analyses: ABCA1-4, ABCA7, and ABCA 12-13 form one group, and ABCA5, 6, 8, 9, 10 belong to the other. Two members in this group, ABCA1 and ABCA4 have been studied in detail. Mutations in the human ABCA1 gene cause Tangier disease (Hoffman and Fredrickson, 1965), which is characterized by deficient efflux of lipids from macrophages and absence of high-density lipoprotein (HDL) cholesterol in the plasma, suggesting its roles in cholesterol and phospholipids efflux (Young and Fielding, 1999). Other studies indicate that the human ABCA1 may be involved in the process of clearance of cells dying by apoptosis. ABCA1 transcripts are upregulated in the macrophages recruited to areas of developmental cell death (Luciani and Chimini, 1996). The *in vivo* loss-of-function and *in vitro* gain-of-function experiments further established its role in the engulfment of dead cells. ABC1-deficient macrophages show an impaired ability of engulfing apoptotic preys, a phenotype that could be suppressed by the acquisition of phagocytic behavior by ABC1 transfectants (Hamon *et al*., 2000). The human ABCA4 gene encodes the rod and cone photoreceptor Rim protein functioning in the transport of retinol (Vitamin A) derivatives from the photoreceptor outer segment disks into the cytoplasma (Koenekoop, 2003). Mutations in the ABCA4 gene have been linked to multiple eye disorders (Allikmets, 2000).
- The ABCB subfamily can be divided further into four distinct functional groups. The largest group, Pgp subfamily, consists of ABCB1, ABCB4, ABCB5, and ABCB11. These proteins, encoding a broad specificity efflux pump

P-glycoprotein (Pgp), have been suggested to be responsible for multidrug resistance in human cells (Ambudkar *et al*., 2003). ABCB1 (MDR1) was the first human ABC transporter characterized (Juliano and Ling, 1976) and was demonstrated to transport hydrophobic substrates such as drugs, xenobiotics, and steroids (Ambudkar *et al*., 2003). In the epithelial cells of the gastrointestinal tract, liver, and kidney, and capillaries of the brain, testes, and ovaries, ABCB1 acts as a barrier to the uptake of toxic metabolites, and promotes their excretion in the bile and urine. ABCB1 also affects the pharmacokinetics of many commonly used drugs, including anticancer drugs (Hoffmeyer *et al*., 2000). The ABCB2, ABCB3, and ABCB9 form a cluster, TAP, and are involved in eukaryotic peptide export. The ABCB2 and ABCB3 form heterodimers to translocate peptides generated by the proteosome into the endoplasmic reticulum (Abele and Tampe, 1999). ABCC9 was found to be associated with lysosomes (Zhang *et al*., 2000). The HMT cluster, including ABCB6 and ABCB7, contains homologs to the yeast ATM1 gene, which is essential for the transport of iron-sulfur clusters from the mitochondrial matrix to the cytosol and, therefore, involved in the maintenance of mitochondrial ion homeostasis (Lill and Kispal, 2001). The MDL cluster includes another group of mitochondrial ABC transporters (ABCB8 and ABCB10). These are homologs to the yeast MDL1 and MDL2 genes, which have been suggested to be involved in the mitochondrial peptide export process (Young *et al*., 2001).

- The ABCC subfamily contains 12 members distributed to two major branches on the tree, which are involved in the efflux of organic anions and drugs conjugated with anionic molecules such as glutathione or glucuronide derivatives (ABCC1, ABCC4, ABCC5, etc.) (Kruh and Belinsky, 2003), chloride ion channel formation (ABCC7/CFTR) (Kleizen *et al*., 2000), and ion channel regulation (ABCC8 and ABCC9) (Gribble and Reimann, 2003). Cystic fibrosis, one of the most common inherited human diseases (Quinton, 1999), is caused by mutations in ABCC7 (CFTR) (Riordan *et al*., 1989), which forms an anion-selective channel functioning in epithelial chloride transport. ABCC8 (SUR1) is a high-affinity receptor for sulfonylurea, a class of drugs used to increase insulin secretion. It regulates the ATP-sensitive potassium (K-ATP) channels in pancreatic β-cells (Ashcroft, 2000). ABCC9 (SUR2) is an isoform of ABCC8 and expressed more ubiquitously (Isomoto *et al*., 1996). One additional member, ABCC13, is a pseudogene that encodes a truncated protein instead of a functional ABC protein, therefore, is not included in our analysis (Annilo and Dean, 2004).
- The ABCD subfamily includes four homologs to the adrenoleukodystrophy protein ALDp (ABCD1), which is defective in X chromosome–linked adrenoleukodystrophy (ALD), a neurodegenerative disorder with impaired peroxisomal oxidation of very long chain fatty acids (Mosser *et al*., 1993). It has been proposed that the function of these transporters is the export of very long chain fatty acids.
- The ABCG subfamily consists of five proteins homologous to the *Drosophila* white, brown, and scarlet genes, which are involved in the transport of eye pigment precursors, such as guanine and tryptophan (Chen *et al*., 1996). ABCG1 is highly induced in lipid-loaded macrophages, suggesting a role in cholesterol and phospholipids trafficking (Klucken *et al*., 2000).

Table 2 Comparisons of the ABC-type transporter subfamilies in eukaryotic species

	Human[a,b]	*Drosophila*[a,b]	*C. elegans*[a]	*Arabidopsis*[a,c]	*A. gambiae*[d]	*Dictyostelium*[e]	*P. falciparum*[a]	*E. cuniculi*[a,f]	*C. parvum*[a]	*C. merolae*[a]	*A. fumigatus*[a]	*S. cerevisiae*[a]
ABCA	12	11	6	12	6	12	0	0	0	2	1	0
ABCB	11	8	21	27	5	9	7	6	1	6	13	4
ABCC	12	13	6	16	14	14	3	0	10	2	12	7
ABCD	4	2	5	2	1	3	0	0	1	3	2	2
ABCG	5	14	9	44	12	21	1	5	1	8	15	10
Others	0	3	1	9	2	3	0	0	0	7	2	1
Total	44	51	48	110	40	62	11	11	13	27	45	24

[a]Ren *et al*. (2004).
[b]Dean *et al*. (2001).
[c]Sanchez-Fernandez *et al*. (2001).
[d]Roth *et al*. (2003).
[e]Anjard *et al*. (2002).
[f]Cornillot *et al*. (2002).

Two other subfamilies, ABCE (RNase L inhibitor) (Bisbal *et al*., 1995) and ABCF (yeast protein GCN20 that mediates the activation of the eIF-2 alpha kinase) (Marton *et al*., 1997), do not exhibit any transmembrane segments and are not involved in transport processes. Therefore, these families are not included in this analysis.

Table 2 compares the number of ABC transporters in different subfamilies. Humans do not have significantly higher number of transporters than other eukaryotes. *Arabidopsis* exhibits the largest inventory of ABC transporters, twice as many as in human, *Drosophila* and *C. elegans*, which reflects the extraordinary metabolite versatility of plants and the requirement of exporting the large complement of toxic secondary metabolites out of the compartments against the steep concentration gradients. *Arabidopsis* ABC transporters are also involved in chlorophyll biosynthesis, formation of Fe/S clusters, stomatal movement, and probably ion fluxes, suggesting their central roles in many plant growth and developmental processes (Martinoia *et al*., 2002; Rea *et al*., 1998). *Arabidopsis* also has a dominant number of transporters in each individual subfamily except ABCD. Intracellular parasites, such as *E. cuniculi*, *C. parvum*, and *P. falciparum*, possess the lowest number of ABC transporters, with the apparent loss or reduction in ABCA and ABCD subfamilies. ABCB, ABCC, and ABCG subfamilies are widely distributed across all eukaryotic species analyzed except the lack of ABCC transporters in *E. cuniculi*, suggesting an essential role for these transporters in all eukaryotes. The degree of gene expansion varies for different subfamilies in different species. For example, the ABCD subfamily is greatly expanded in *Arabidopsis,* with almost 10 times as many subfamily members as in humans, while humans and *Arabidopsis* have a similar number of ABCC subfamily transporters. *Anopheles gambiae* appears to have less proteins belonging to the ABCA and ABCB subfamilies compared to *Drosophila* and humans, but the ABCG subfamily genes are expanded, leading to twice as many subfamily members as in humans. The comparisons of ABC transporter subfamilies in different organisms indicate that the ABC superfamily evolved by a gene "birth-and-death" process (Dean *et al*., 2001). The constituents of the ABC subfamilies are generated by gene duplications. Some of the genes persist and develop highly specific functions, while others are deleted or become nonfunctional pseudogenes, like ABCC13 (Annilo and Dean, 2004).

The discussion of the ABC transporter family presented here is an example of a detailed phylogenomic analysis of one transporter family and the type of the insights that this style of analysis reveals. With the complete transporter data from 141 sequenced species, we have been able to conduct phylogenomic analyses on all 134 transporter families. The phylogenetic trees of all these families are available from the TransportDB website (**http://www.membranetransport.org/**). Such approaches will help to reconstruct the evolutionary history of a family, and to investigate instances of gene loss, lateral gene transfer, and gene duplications and expansions. These analyses could also assist in the prediction of the structure, mechanism, and function of unknown transporters.

In summary, a comprehensive classification system for transporter proteins (TCDB), and a complete transporter system comparison database for sequenced genome (TransportDB) have been built up, aimed to include all membrane transport systems found in all living organisms. The advantage of the incorporation of phylogeny into the classification system and the importance of a phylogenetic

approach are underlined by the fact that phylogeny provides reliable guide to structure, function, and mechanism of transporter proteins, and supplies valuable information on the evolutionary history of a family.

Specialist Review

Structure comparison and protein structure classifications

Oliver Redfern, Christopher Bennett and Christine Orengo
University College London, London, UK

1. Introduction

Evolution has given rise to families of homologous proteins that appear to be related to a common ancestral gene. As mutations occur and new proteins evolve, amino acids sequences may change dramatically. However, protein structure can remain much more highly conserved and it is possible to identify distant evolutionary relatives by comparing their structures. This chapter outlines some of the concepts behind the methods used to classify known protein structures into families. There are numerous protein structure classifications and we discuss and contrast the implementations of the various structure comparison and classification methodologies used to create them.

Perhaps the most important rationale for creating structural databases is that as structure is so much more highly conserved during evolution than sequence, one can recognize very distant relatives, undetectable by sequence comparison. Although the recent development of very powerful sequence profiles and Hidden Markov Models have improved the recognition of distant homologs, visual inspection of the structures of remote homologs greatly aids validation. Some distant homologs are only detectable by structure comparison methods (see Section 6.2). Furthermore, recognition of individual domains within proteins is much more easily achieved by manual examination of the structure.

All structural classifications are based on the solved protein structures deposited in the Protein Structure Databank (PDB, Berman *et al*., 2002). This was established in 1971 and was originally based at the Brookhaven National Laboratories, USA. Since 1998, the PDB has been maintained by the Research Collaboratory of Structural Biology (RCSB), **http://www.rcsb.org/pdb/**. There is also a European node, the Macromolecular Structure Database (MSD), based at the European Bioinformatics Institute in the United Kingdom, **http://www.ebi.ac.uk/msd/**. As of July 2004, the PDB contains ~25 000 entries and currently around 500 new structures are deposited monthly. This number is expected to increase as the structural genomics initiatives become more productive.

Table 1 Table of the most widely used protein structure family database and descriptions of the methods used to create them

Database	Location and author	Coverage (July, 2004)	Structure comparison method	Type	Description	URL
CAMPASS	Cambridge University, UK, Sowdhamini	7580 domains in 1409 superfamilies	COMPARER (Sali and Blundell, 1990), SEA (Rufino and Blundell, 1994)	Structure-based sequence alignments of SCOP superfamilies.	CAMbridge database of Protein Alignment organized as Structural Superfamilies. Provides sequence alignments of structural domains within a superfamily.	**http://www-cryst.bioc.cam.ac.uk/~campass/**
CATH Gene3D	UCL, London, UK, Orengo	58 000 domains in 1459 superfamilies	SSAP (Taylor and Orengo, 1989), GRATH (Harrison *et al.*, 2002)	Automatic structural and sequence comparison methods are combined with manual validation of superfamily alignments and domain boundaries.	CATH is a hierarchical classification of protein domains structures, clustered by Class, Architecture, Topology and Homologous Superfamily.	**http://www.biochem.ucl.ac.uk/bsm/cath/**
CE	SDSC, La Jolla, CA, USA, Bourne	All chains in PDB	CE (Shindyalov and Bourne, 1998)	Fully automatic. Nearest neighbors.	Combinatorial Extension of the optimal path. A database of structural alignments and similarities between all structures in the PDB.	**http://cl.sdsc.edu/ce.html**

DHS	UCL, London, UK	1459 superfamilies in CATH	SSAP (Taylor and Orengo, 1989) CORA (Orengo, 1999)	Fully automatic multiple structure alignments of close relatives in CATH superfamilies.	Dictionary of Homologous Superfamilies. Multiple structure alignments of homologous domains as defined by superfamilies in the CATH database. These are further annotated with functional information from UniProt, ENZYME, GO, KEGG.	**http://www.biochem.ucl.ac.uk/bsm/dhs/**
ENTREZ/MMDB	NCBI, Bethesda, MD, USA, Bryant	All in PDB	VAST (Madej *et al.*, 1995)	Fully automatic. Nearest neighbors.	MMDB contains precalculated pairwise structural comparisons and alignment between all structures in the PDB.	**http://www.ncbi.nih.gov/Structure/MMDB/mmdb.shtml**
HOMSTRAD	Cambridge University, UK, Blundell	7500 domains in over 1400 superfamilies	COMPARER (Sali and Blundell, 1990)	Manual classification of close protein homologs.	HOMologous STRucture Alignment Database, Database of annotated structural alignments for homologous protein families, utilizing SCOP, Pfam, and SMART to identify relatives.	**http://www-cryst.bioc.cam.ac.uk/~homstrad/**
SCOP SUPERFAMILY	LMB-MRC, Cambridge, UK, Murzin	54 745 domains in 1294 superfamilies	Manual	Manual classification.	Structural Classification Of Proteins. Hierarchical classification by Class, Fold, Superfamily, Family.	**http://scop.mrc-lmb.cam.ac.uk/scop/**

The first structural classifications became available in the early 1990s (Swindells *et al*., 1998) when enough structures were available in the PDB to organize them into evolutionary families and fold groups. Table 1 lists the most comprehensive structural family databases and structural neighborhood resources accessible over the Web, together with a summary of any distinctive features used in generating, validating, and curating them. This chapter will focus on generic protocols that are common to all the major classifications and then highlight individual resources where approaches have been adopted that differ to the common protocols.

2. The hierarchy of domain structure classifications

Most databases adopt a hierarchical classification of protein domain structures (see Figure 1). The top level is the class of the protein, which is assigned depending on the percentage of residues that adopt α-helical or β-strand conformations. There are generally three types of class, mainly-α, mainly-β, or a mixture of the two, $\alpha-\beta$. In some databases (e.g., Structural Classification of Proteins, SCOP), the $\alpha-\beta$

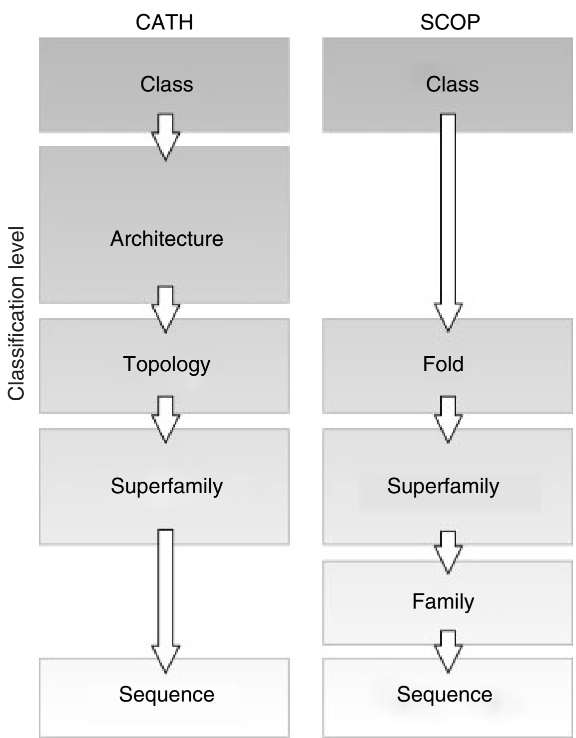

Figure 1 Schematic comparison of the SCOP and CATH hierarchical structure classifications. SCOP recognizes four major classes (mainly α, β, α/β, and $\alpha+\beta$), whereas CATH combines the 2 $\alpha-\beta$ classes. The fold level of SCOP is equivalent to the topology level in CATH; however, SCOP then groups homologs more closely into families, while CATH groups more distant relatives into superfamilies

class is further divided into alternating α/β and $\alpha+\beta$. Within each class, proteins are subclustered according to their fold. The fold describes the relative orientations of the secondary structures and their connectivity; that is, the order in which they appear along the polypeptide chain.

In the CATH database, an additional architecture level is assigned between class and fold, depending on the relative orientations of the secondary structures. Architecture effectively describes the overall shape adopted by the protein domain. For example, within the $\alpha-\beta$ class, two very popular architectures are the $\alpha-\beta$ barrel and the 3-layer $\alpha-\beta$ sandwich. Within each fold group, domains sharing a common evolutionary ancestor are then grouped into homologous superfamilies. SCOP divides these into families. Some resources further subcluster automatically within each superfamily to group domains according to significant levels of sequence similarity (e.g., 30, 60, 95%). Figure 1 compares the CATH and SCOP classifications.

3. Methods used to classify structures

There are a number of automated and semi-automated stages in the classification of structures. First, since most structural classifications are based on domain similarities and since nearly 40% of all known structures in the PDB comprise multidomain protein chains, it is necessary to divide the protein chain into its constituent domain regions. Next, homologous domains must be identified. For close relatives, this can be achieved using standard sequence alignment methods and 1D-profiles (see below).

More distantly related domains can often only be recognized by employing sensitive structure comparison methods. Those structures sharing other features besides structural similarity, for example, rare sequence motifs or functional properties, are likely to have diverged from a common ancestor and can be classified into the same homologous superfamily. Similarly, those sharing only structural similarity are clustered into fold groups. It is possible to reliably assign class using automated methods but architectures are usually described following visual inspection.

The concepts behind the algorithms used in the different stages of classification are outlined in more detail below.

4. Domain boundary assignment

Most multidomain proteins comprise two domains although up to eight domains are observed in some chains. In the majority of cases, each domain is associated with a compact globular arrangement of secondary structures comprising a single fold. Although there are some cases of folds being formed by two or more domain regions from different proteins, these are rare and are sometimes anomalies arising from the manner in which the proteins have been divided for structure determination.

It is likely that the proportion of multidomain structures solved will increase as the structural genomics initiatives progress. Analyses of sequences from completed

genomes by Teichmann and co-workers (Apic *et al*., 2001) have suggested that up to 60% of sequences in prokaryotes are multidomain. This proportion rises to nearly 80% in eukaryotes.

A significant minority of domains (>20%, Pearl *et al*., 2002) occurring in multidomain contexts are discontiguous in sequence, that is, they comprise separate regions of the polypeptide chain and probably arise from domain insertions during evolution. This can considerably complicate the automatic detection of domain boundaries and is particularly problematic for sequence-based methods. More accurate boundary placement can be achieved using the structural data since visual inspection allows boundary refinement in difficult cases.

There have been several successful approaches to recognizing domain boundaries automatically from structure (see Pearl and Orengo, 2003). In most multidomain proteins, the majority of residue contacts occur in the core of a domain, with relatively few contacts between domains. A number of algorithms (DOMAK, PUU) explore alternative divisions of the protein chain that optimize the number of contacts within domains and minimize contacts between domains. Since internal contacts frequently involve compactly packed hydrophobic residues, some methods (e.g., DETECTIVE, Swindells, 1995) attempt to identify domains by locating hydrophobic clusters, which are then expanded until the packing density falls.

More sophisticated approaches developed recently, such as STRDL (Wernisch *et al*., 1999) and DOMS (Taylor, 1999), use different methods but achieve similar success rates. STRDL (STRuctural Domain Limits) uses the Kernigham–Lin graph heuristic to partition a protein chain into sets of residues between which there are minimal interactions – deduced from a weighted Voronoi diagram. Putative partitions are scored on the basis of how well their physical properties fit those of known structural domains.

Most of the algorithms perform well for simple multidomain structures in which the separate domains have minimal contact. However, for more complex chains in which domains are more intimately connected or discontiguous, the performance is less notable. Despite recent improvements, most methods only correctly distinguish proteins as single or multidomain in 80–90% of cases, when tested using manually validated datasets from SCOP and CATH (Jones *et al*., 1998). The success rate falls to 70–80% when assessing the fidelity of residue ranges of assigned domains. Some domains belonging to the most highly populated families (e.g., TIM barrels) are split by many of the methods. A consensus approach (DBS, Jones *et al*., 1998) developed for the CATH database, which sought consensus between three independent methods (DOMAK, PUU, Detective) found that these methods only agreed within reasonable limits 55% of the time.

In particular, automatic methods for discerning domain boundaries are hindered by the lack of any clear quantitative definition of a domain. Domains were first suggested to be independent folding units by Richardson (1981). Subsequently, various qualitative definitions exist, for example, the following criteria are often used in assessing domain regions within a structure:

- The domain possesses a compact globular structure.
- Residues within a domain make more internal contacts than residues in the rest of the polypeptide.

- Secondary structure elements are usually not shared with other regions of the polypeptide.
- There is evidence for existence of this region as an evolutionary unit. For example, in other structural contexts (i.e., different multidomain structures) or as a single domain.

This latter concept of recurrence is used strictly in generating the SCOP classification and domains are identified manually by visually inspecting the structures. In the DALI Domain Database (DDD), an automatic algorithm (PUU) is used to identify putative domains, which are then validated by searching for recurrences in other structures.

Other resources (e.g., CATH, ENTREZ, RCSB) also exploit the fact that the majority of domains recur in different contexts and therefore use structure comparison techniques to locate fold matches within multidomain proteins using a nonredundant library of preclassified folds. These techniques are becoming increasingly successful as the fold libraries expand. Nearly 95% of newly determined domain structures are related to structures already classified in CATH. This proportion is likely to increase as structural genomics initiatives progress as they are specifically targeting novel folds, thereby increasing the fold repertoire (this is also discussed below).

Although no method achieves 100% accuracy in locating precise domain boundaries, the automated approaches significantly assist in locating domains within newly determined protein structures and thereby reduce the amount of manual inspection that is required. Putative boundary definitions can be refined by manual inspection using graphical representations. Programs such as RASMOL (**http://www.openrasmol.org/**), Protein Explorer (**http://www.umass.edu/microbio/rasmol/**) and PyMol (**http://pymol.sourceforge.net/**) are freely available and provide excellent 3D representations of protein structures that can be easily rotated.

5. Identifying close relatives by sequence-based methods

Currently, at least 90% of structures in the PDB are nearly identical (>90% sequence identity) to another structure. This redundancy results from interest in solving relatives with mutated residues in order to determine the impact of these mutations on the stability and functions of the proteins. For example, there are around 844 mutant lysozyme structures in the PDB. In some families, there are also identical or near-identical structures solved with different ligands bound.

Figure 2 shows the distribution of pairwise sequence identities between all nonredundant homologs from the CATH database (release 2.51, 2004). Relatives within a family tend to be highly similar or quite remote (<30% sequence identity) as structural biologists have frequently targeted proteins that appear to have no homologs in the PDB and may thus possess novel folds.

However, as the sequence and structure databases grow and sequence comparison methods become increasingly sophisticated, a significant proportion of newly determined structures each year can be putatively assigned to a structural family

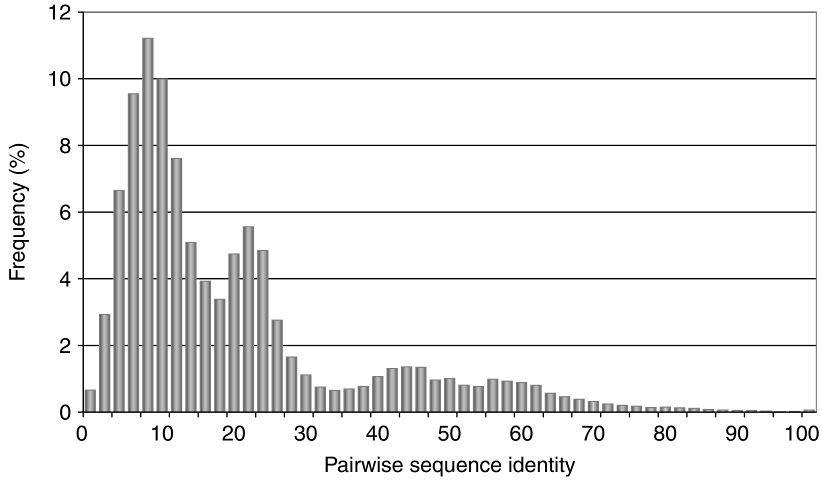

Figure 2 Graph showing the frequency of sequence identities between pairs of homologous domains. It can be seen that the majority of homologs in the PDB show less than 25% sequence identity

based purely on sequence information (discussed in more detail below). This is important as structure comparison can be more than an order of magnitude slower than sequence comparison and in order to keep pace with all the new structures being deposited, it is essential to use rapid sequence methods as a filter for identifying clear homologs.

Sequence-based methods for homolog recognition are well established and are described in some detail in other chapters of this volume. Most resources exploit fast-search algorithms like BLAST or FASTA to identify a putative family to which a new structure may be assigned. Subsequently, slower comparisons using various implementations of the Smith–Waterman or Needleman–Wunsch algorithms are run against all nonredundant structures in the family to obtain more accurate alignments for sequence subclustering within superfamilies.

However, in using these approaches, it is important to check the degree of overlap between any query and matched structure as there may be additional unmatched domains in one or other protein if they are multidomain structures. Details on thresholds used by the different groups in clustering homologs vary for different resources but require overlap values of 60% for remote homologs and up to 80% for close homologs.

For remote homologs the recent generation of 1D-profile–based methods such as PSI-BLAST (Altschul *et al*., 1997) and IMPALA (see Lee *et al*., 2003 for a review) are often used. These use multiple relatives from a family to derive a sequence profile that encodes patterns of highly conserved residues that may be important for stability and function. There are many pattern or profile-based techniques that have been developed to recognize relatives of sequence-based families (e.g., InterPro, SMART, PRINTS, Pfam) and readers are directed to chapters? for further details.

Hidden Markov models, as implemented in the SAM-T9x technology of the Karplus group (Karplus and Hu, 2001) have recently been shown to be even more

powerful than many of the 1D-profile methods at recognizing remote homologs. They also perform better in the recognition of discontiguous domains. Chothia and co-workers have pioneered the use of structural databases (e.g., SCOP) to assess the percentage of remote homologs that can be recognized using these approaches. Similar results have been obtained by benchmarking the methods using the CATH database (Salamov *et al*., 1999; Pearl *et al*., 2000). In a recent analysis using manually validated homologs from the CATH database (release 2.5.1), at least 80% of these remote homologs could be recognized with a low error rate (<0.1%).

Use of large intermediate sequence libraries can also help in pushing the limits of homolog detection. To create these libraries, several structural classifications have recruited hundreds of thousands of additional sequence relatives from the genomes and large sequence databases (e.g., UniProt, Apweiler *et al*., 2004), applying the techniques described above, with conservative thresholds. The SUPERFAMILY resource established in 2001 by the SCOP group expands the SCOP database (Gough *et al*., 2001). They have assigned 1232 superfamilies to predicted proteins from 154 completely sequenced genomes, the UniProt database, and other sequence collections. Close to 60% of all proteins have at least one match.

The Gene3D resource provides an equivalent library of 854 000 sequence relatives for CATH families. This gives 27 000 additional sequence families (clustered at 35% sequence identity). By building Hidden Markov models from representatives of each sequence family, it is possible to increase the percentage of remote CATH homologs recognized to 85% (Sillitoe *et al*., 2004). As the sequence databases expand, these methods will clearly become even more sensitive.

Importantly, a large proportion of newly determined protein structures can now be identified using sequence-based methods, both pairwise and profile based. Over the last few years, nearly 80% of new structures with relatives already classified in the structure databases, can be recognized in this way. However, structures solved by the structural genomics consortia have often been targeted by excluding very remote homologs, using the profile-based methods. Therefore, a smaller proportion of these structures can be recognized in this way and structure comparison methods must be used.

6. Structure-based methods for recognizing remote homologs and analogs

As two proteins diverge from a common ancestor, their sequences can change beyond recognition. However, their three-dimensional structures usually remain similar. This was originally demonstrated by Chothia and Lesk (1986) who plotted sequence similarity against structural similarity for homologs in the PDB. A more recent analysis (Orengo *et al*., 2001) of several hundred well-populated superfamilies in the CATH database, containing three or more sequence families, confirmed that even in very remote relatives (<20% sequence identity), at least 50% of the structure remains conserved. The most highly conserved positions usually correspond to residues in secondary structures, in the buried core of the protein.

Structural comparison methods were introduced in the 1970s, shortly after the advent of the Protein Databank (PDB). Although they can be used to superpose

entire multidomain chains, it is often useful to separate proteins into their constituent domains, as the connectivity and orientation of domains can vary widely and this can have negative effects on the quality of the structural alignment.

There are well over 50 different structure comparison algorithms cited to date but many are variations on a number of techniques. In general, they perform the alignment in two stages. Some measure of similarity of residues and/or secondary structure features between both proteins is calculated and a subsequent optimization strategy is employed to find the alignment that maximizes these similarities. The majority of methods use geometric properties of the C_α or C_β atoms and/or secondary structure information, such as distances or intramolecular vectors. Physicochemical properties, such as hydrophobicity, hydrogen bonding and disulfide bonding, are sometimes utilized. However, they can be of limited use and create unnecessary noise in the alignment.

6.1. *Calculating structural similarity*

Irrespective of the method used to align or superpose two protein structures, some quantitative measure of similarity is needed. The most widely used of these is the Root Mean Square Deviation (RMSD). This is simply the square root of the average squared distance between equivalent atoms as defined by

$$RMSD = \sqrt{\frac{\sum_{i=1}^{N} {d_i}^2}{N}}$$

Similar proteins folds tend to give an RMSD below 4.0; however, this can be higher for distant relatives with more than 400 residues. This highlights the main problem with using RMSD as a measure of similarity; namely, that it is dependent on the size of the proteins being aligned (in the equation above). It is therefore important to consider both the RMSD and the number of equivalent residue pairs when assessing the significance of the similarity. Despite its limitations, RMSD remains a widely used and valuable measure. As with sequence-searching tools, most structural comparison methods have developed more rigorous statistical methods for database searching, discussed below.

6.2. *Structure comparison algorithms*

There are now many structure alignment algorithms (see Sillitoe and Orengo, 2003, for a review), in this chapter, we review the main concepts involved and discuss in more detail those most frequently used to identify homologs in the structural classifications listed in Table 1.

6.2.1. Rigid body superposition methods

It is possible to treat two protein structures as rigid objects and think of superposition as finding the best way of fitting one on top of the other, so there is

a minimum difference between them. It should be noted that this is distinct from structural alignment methods, which map equivalent residues between two proteins. This was the rational of the first methods pioneered by Rossman and Argos in the 1970s. Rigid body superposition can be thought of in the following three stages:

1. translating structures to a common position in the coordinate frame, usually by translating their center of mass to the origin;
2. finding putative equivalent positions to start the optimization;
3. rotating one protein, relative to the other, around to three major axes to look for the "best fit".

The major difficulty with this method lies in identifying putative equivalent positions to begin the optimization. For close relatives (>35% sequence identity), standard sequence alignment methods can be used. However, for more distantly related proteins, this is unreliable and the algorithm often requires manual inspection to define known equivalent residues, such as catalytic residues in the active site.

Therefore, rigid body superposition is generally only used to compare closely related proteins or to superpose structures once alternative algorithms, able to handle extensive insertions and deletions, have determined through structural alignment equivalent positions (see below).

6.2.2. Secondary structure-based methods

One approach to handling insertions/deletions (indels) in distant homologs is to simply compare the secondary structures as most indels occur in the loops connecting secondary structures. Graph theoretical methods tend to dominate this approach to secondary structure comparison, as they are fast and effective. Most concentrate on the distances and angles between secondary structures in both proteins, which are compared to find equivalent pairs (see Figure 3).

6.2.2.1. GRATH, SSM

Graph theory is a significant branch of mathematics that has been applied to many different areas of biology and computer science. A graph consists of points, or *nodes*, in two-dimensional space connected by lines, or *edges*, that describe the relationship between them. A protein structure can be reduced to a graph where the nodes are secondary structures and the edges describe the geometric relationships between them (e.g., distances, angles). Artymiuk and co-workers were the first to use these techniques in 1993, although Harrison *et al*. (2002) have applied them more recently to detect fold similarities as part of classification in the CATH database (GRATH).

Linear vectors are used to represent the secondary structures and then edges are labeled with distances between the midpoints and angles, describing the tilt and rotation between the vectors. The resulting two protein graphs are then evaluated to look for common secondary structure "cliques or subgraphs", by identifying equivalent edges that are labeled with similar distances and angles (see Figure 3).

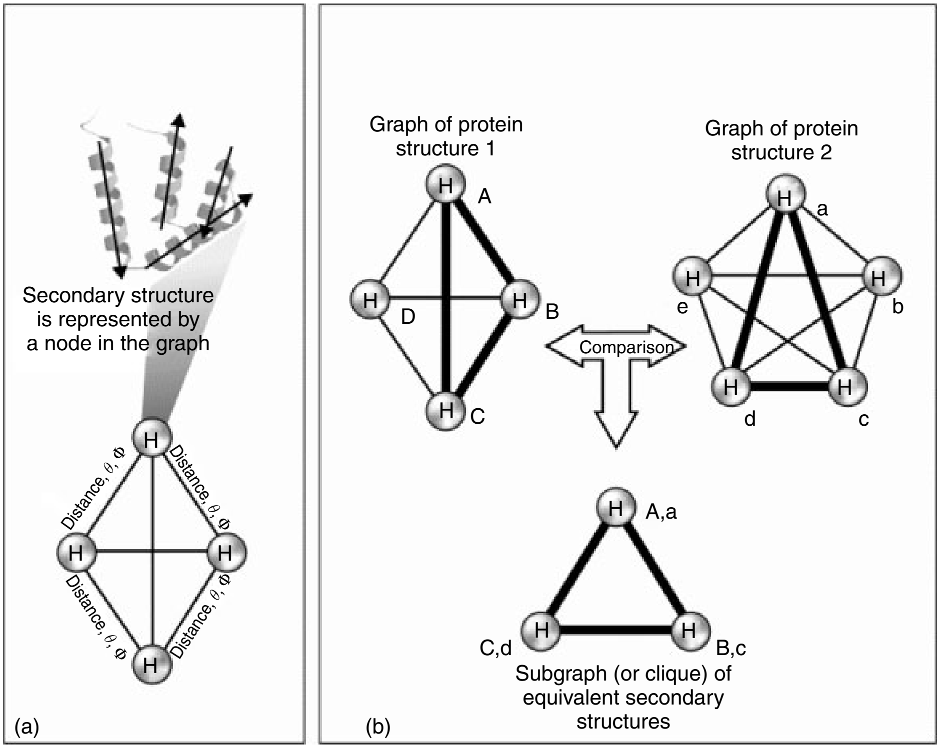

Figure 3 Illustration of graph theory–based structure comparison algorithms. (a) Linear vectors are calculated through each secondary structure and used to represent each node in a graph. The relationships between these vectors (e.g., angles and midpoint distances) then annotate the edges between them. (b) Two protein graphs are compared by looking for equivalent edges (highlighted in bold). Whereas SSM looks only for common subgraphs, GRATH looks for fully connected cliques. The resulting secondary structure graphs can represent a common topology shared by the two protein domains

At the European Bioinformatics Institute (EBI) in Cambridge, UK, Krissinel and co-workers (Krissinel and Henrick, 2004) have optimized a subgraph matching algorithm, on which they base their SSM method. Much like GRATH, it labels edges with distances and angles to determine equivalent relationships. However, a greater emphasis is placed on the similarity between the sizes of secondary structures. The major difference is that SSM does not search for fully connected cliques. This is compensated for by also looking for equivalent connectivity, that is, matched secondary structures must be in the same order along the protein chain.

These methods are extremely fast (particularly with <20 secondary structures) at searching databases of folds and very effective at identifying distant fold similarities. They are often used to find putative structural relatives that can then be aligned more accurately to the query structure using residue-based methods.

6.2.2.2. VAST

Entrez at the NCBI provides a Web resource of structural alignments and superpositions of around 10 000 domain substructures within the PDB using the

VAST (Vector Alignment Search Tool) algorithm (Madej *et al*., 1995). In a similar way to graph theory methods, VAST focuses on the relationship between secondary structures. They define "units" of tertiary structure similarity as pairs of secondary structure elements that share a similar type, relative orientation, and connectivity. Two protein domains are aligned to give the optimal superposition score across all pairs of secondary structure elements (SSEs). A statistical method is then employed to measure the likelihood that this similarity would be seen by chance, by calculating the probability that the score would be obtained when random pairs of SSE combinations between the two domains were superposed. The method yields a significance score that appears to be highly discriminatory at identifying structural relatives.

6.2.3. Residue distance and contact map–based methods

Some of the earliest structural comparison methods were based on distance plots. These are 2D matrices that are shaded according to the distances between residues in a protein. In a similar vein, contact maps, which record those residues that are in contact (within a threshold distance ∼8Å), can also be generated. These contacts can be based on C_α atoms only or other atoms in the residue side chains. The patterns that arise in the resulting matrix are often characteristic of a particular protein fold. For example, dense stretches of contacts indicate closely packed secondary structures. Protein structures can be aligned by overlaying their contact maps. However, as with rigid body methods, it is difficult to overlay the maps of distant homologs and various strategies have evolved to cope with extensive insertions/deletions.

6.2.3.1. DALI and CE

One approach to aligning distant structural relatives is to divide each protein into fragments. CE and DALI are popular examples of this method that involves finding equivalent fragments and then combining them to form an overall alignment, using some form of optimization strategy.

Holm and Sander developed the DALI algorithm (see Figure 4), which fragments the proteins into hexapeptides and then uses contact maps to compare them. Potentially equivalent fragments are identified by looking for similar patterns of distances between residues, within a specific threshold. These pairs are then concatenated to extend the alignment using a Monte Carlo optimization. RMSD is used to assess the quality of the extension as the concatenation progresses.

CE fragments the polypeptide chain into octapeptides and aligns residues on the basis of characteristics of their local geometry (as defined by vectors between C_α positions). Matching fragments are termed *aligned fragment pairs* (*AFPs*). Heuristics are used to define a set of optimal paths joining AFPs with gaps as needed. The path with the best RMSD is subjected to dynamic programming to achieve an optimal alignment. For specific families of diverse proteins, additional characteristics are used to weight the alignment.

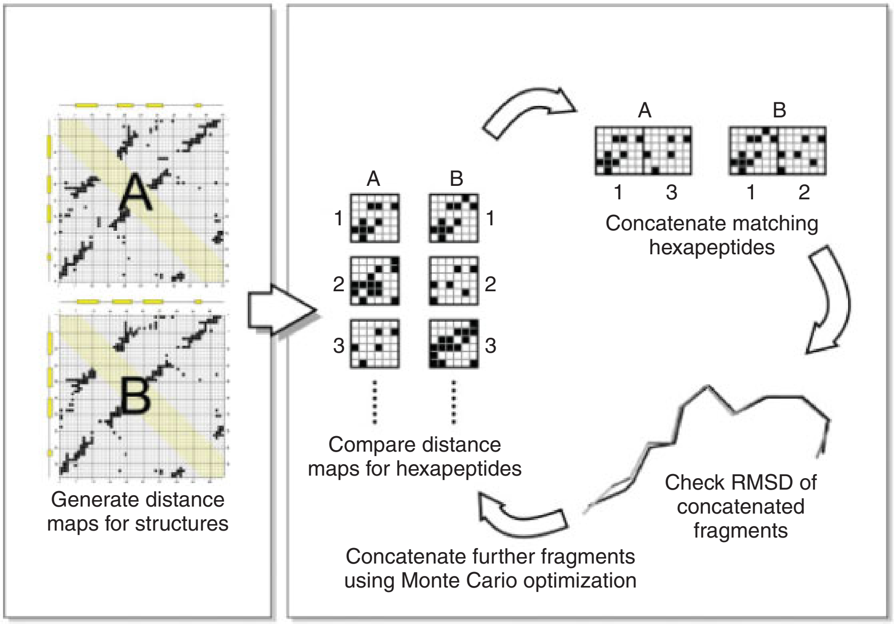

Figure 4 The DALI method of Holm and Sander. Proteins are fragmented into hexapeptides and their contact maps compared to find equivalent fragments. Fragments are concatenated and their RMSD checked to find valid extensions. Monte Carlo optimization is used to guide the extension process to a full alignment

6.2.3.2. SSAP

Another approach, based on comparing distances between residues, was developed by Taylor and Orengo (1989). They sought to deal with the structural embellishments observed between distant relatives by applying the dynamic programming techniques used in sequence alignment methods. In the SSAP algorithm, dynamic programming is in fact utilized twice: first, to compare residue views and second, to determine the equivalent residues.

At the heart of the comparison lies the concept of "residues views" (see Figure 5). These are simply vectors calculated between all C_β (side chain carbon) atoms and a specific residue within a structure. These vectors are compared between the two proteins by scoring for similarity. The number of potentially equivalent residues is also limited by selecting on physicochemical and secondary structure properties (e.g., accessibility, phi and psi angles). A "residue-level score matrix" is constructed for each pair of putatively equivalent residues with scores that reflect the similarity of a given pair of vectors. For example, vectors from residue (i) to other residues in protein A are compared to vectors from residue (j) to other residues. Dynamic programming is used to find the optimal high-scoring path through the matrix.

The second step is to amalgamate the information from the residue-level matrices into a summary score matrix. Pairs of residues are selected as being potentially equivalent on the basis of the score of the best path through their residue-level matrix. These optimal paths are collated in the summary matrix and an overall optimal path is calculated using dynamic programming. The SSAP algorithm is

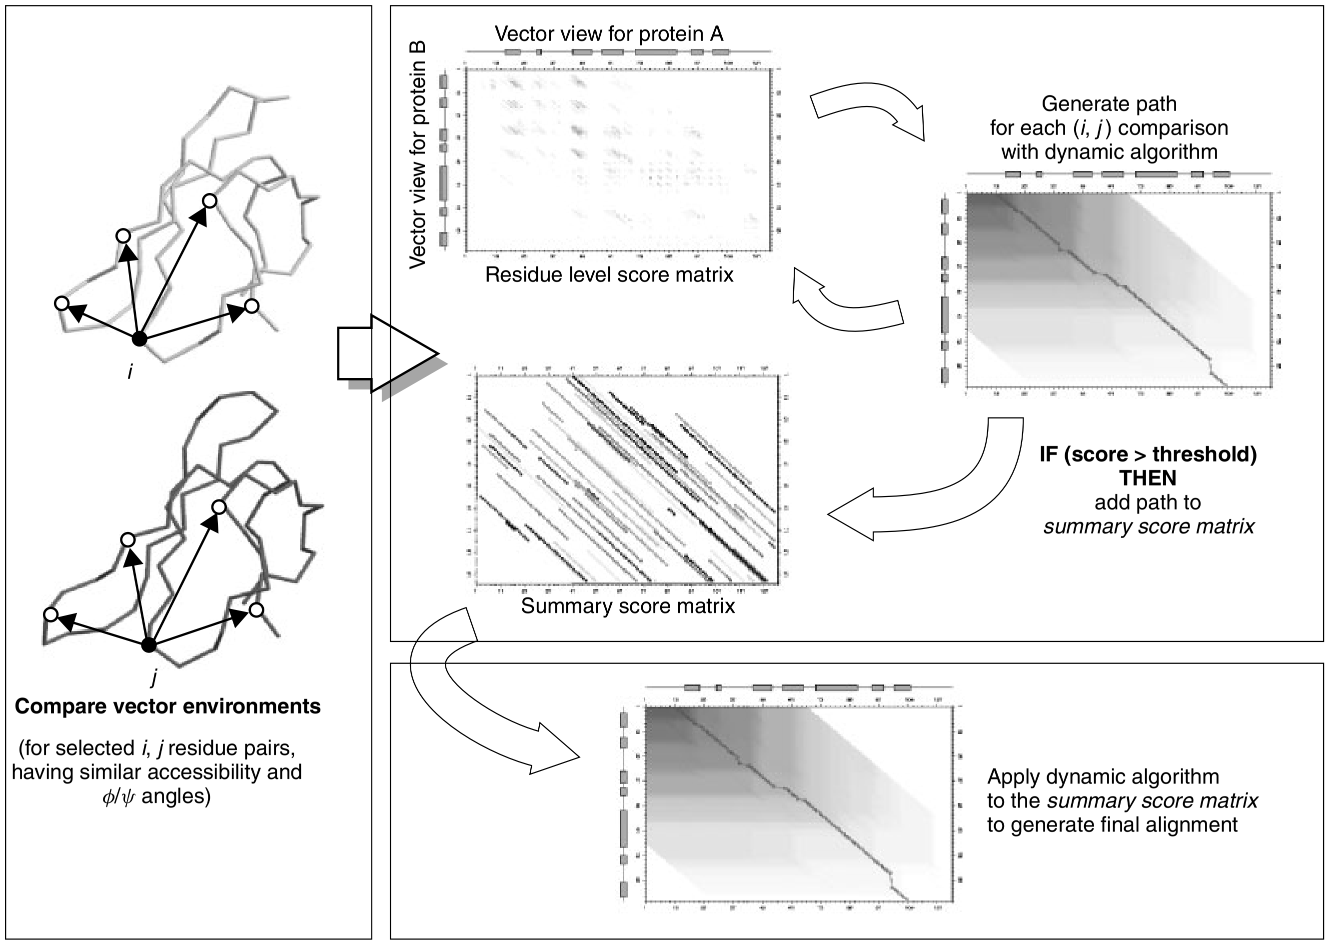

Figure 5 Flowchart of the SSAP algorithm. Vector environments are compared between pairs of potentially equivalent residues in each protein. A residue-level score matrix is constructed for each pair and optimal paths (putative alignments) are calculated by dynamic programming. High-scoring paths are then added to the summary score matrix. Dynamic programming is then applied to the summary matrix to generate the final optimal alignment of the two structures

used to recognize remote homologs for classification in the CATH database (see Table 1).

6.2.3.3. COMPARER

Sali and Blundell (1990) developed COMPARER by using intermolecular superposition and then subsequently assessing relationships between residues within each structure. Properties of residues, such as secondary structure type, side-chain orientations and torsional angles, are then compared between proteins and used to populate a 2D matrix. These are combined with intramolecular information (C_α distances, hydrogen bonding patterns, distances to the protein's center of mass) to find equivalent residues. Putative equivalences are optimized by rigid body superposition followed by a technique known as simulated annealing. This employs the probabilistic Boltzmann energy function, which calculates energy change as temperature decreases to find optimal solutions to superposition of the proteins. The final alignment is then optimized using dynamic programming.

6.3. Assessing structural similarity

Earlier we mentioned how RMSD can be used to assess how closely two structures have been superposed. However, it was highlighted that RMSD is length dependent and therefore the embellishments observed between large structural relatives cause the RMSD to be unrepresentatively high. Moreover, proteins in different folds use a common repertoire of super-secondary structure motifs (e.g., β-hairpins, $\alpha-\beta$ motifs) that can create local similarities that may bias the RMSD.

Workers in the field of structural comparison have taken similar approaches to those used in scanning large sequence databases, by employing statistical methods to provide a more representative score. A commonly used measure is the Z-score. Given a particular structural similarity between putative relatives, the Z-score gives a measure of the number of standard deviations a particular score is from the mean. DALI and CE both use this approach to rank their database scans.

Although Z-scores are often helpful, they are at their most powerful when data follows a normal distribution. However, most database scans follow an extreme value distribution where the highest scores occur at low frequencies. By taking a protein and performing multiple scans of a database, an exponential function can be "fitted" to the latter part of the distribution. This function can then be used to convert each score into a probability. This probability represents the likelihood that the score could have been given by unrelated proteins. By multiplying this probability by the number of structures in the database, it is easy to calculate how many unrelated proteins you would expect to "hit" with a specific score (the expectation or E-value). A low E-value (<1) is a good indication that the query structure has matched a significant structural relative. The GRATH algorithm uses E-values to detect fold similarities for classification in the CATH database.

6.4. Multiple structure comparison

As with using multiple sequence analysis to identify conserved amino acids within a protein family, multiple structure alignments can reveal conserved structural features that may be important for function or fold stability. Within structural superfamilies (see later), relatives tend to exhibit embellishments around a common conserved "core" (see Sillitoe *et al*., 2001 for a review). Capturing that core in a structural fingerprint can provide a more sensitive tool for identifying relatives of that family.

Several of the pairwise algorithms STAMP (Russell and Barton, 1992; COMPARER (Sali and Blundell, 1990)) have been adapted to align sets of structures. The most common strategy is to perform a progressive alignment where the multiple alignments are built from a series of pairwise alignments. Pairwise similarities are first calculated and subjected to hierarchical single-linkage clustering. The subsequent phylogenetic tree defines the order in which structures are added to the alignment. In order to preserve the quality of the alignment, it is common to take the most similar pair of structures first.

6.5. Databases of multiple structure alignments

The HOMSTRAD and CAMPASS databases (see Table 1) aim to provide multiple structural alignments for protein superfamilies. HOMSTRAD uses SCOP, PFAM, and other resources to look for close structural relatives where there is clear evidence from structural comparison (and often high sequence homology) that the proteins are related. Although individual pairwise sequence identities can be as low as 12% in families such as the globins, all the members can be single-linked with a sequence identity of at least 21%. These multiple alignments can be used to derive substitution matrices to calculate residue-exchange matrices or to encode conserved structural features in a template that can be used to identify further relatives. The CAMPASS database groups more distant structural homologs than HOMSTRAD by using the structural comparison algorithms COMPARER and SEA (Rufino and Blundell, 1994) to generate multiple alignments of SCOP superfamilies. Currently, they have around 7500 domains in over 1400 superfamilies.

Alignments from the HOMSTRAD database have been used to derive substitution matrices describing preferences for residue exchange in different structural environments. Although, to date, such matrices have not performed as well as those derived using sequence-based families (e.g., the BLOCKS database for the BLOSUM matrices), recent updates have performed well and as the structure databank expands with the structural genomics initiatives and more diverse representatives are determined, these approaches will become increasingly powerful.

As an alternative to chaining pairwise alignments, other methods (such as CORA; Orengo, 1999) instead build a "consensus structure" at each stage of the alignment to align subsequent structures. This is thought to better preserve the fidelity of the alignment. In the CATH database, the CORA algorithm is used to provide

structural alignments for subgroups of structures in each superfamily sharing a reasonably high degree of structural similarity as assessed by scores returned from the SSAP algorithm. Structural fingerprints or 3D-templates are also generated for each structural subgroup to help improve recognition of distant homologs. Currently, CATH generates ~700 multiple alignments for 498 well-populated domain superfamilies.

7. Structural classification: assigning domains to different levels in the structure classification hierarchy

As already discussed above, most structural classifications have been established at the domain level, since this is generally thought to be an important unit that can participate in the evolution of new functional proteins. Some domains are highly recurrent across the genomes and interesting insights into evolutionary mechanisms can often be gleaned by understanding how relatives in domain families combine with different domain partners to evolve new functions.

Therefore, for classifying new structures, domain boundaries are identified first. This is achieved either by fold recognition algorithms (e.g., DALI, GRATH, SSM, VAST) or if the protein contains novel domains, using ab initio approaches (e.g., PUU, DETECTIVE) and manual inspection. The major classifications show that the current set of structural entries in the PDB comprise between 50 000–60 000 domains (SCOP – 20 619 entries, 54 745 domains; CATH – 22 303 entries, 58 141 domains).

Subsequently, close relatives are identified using standard pairwise methods (e.g., BLAST, SSEARCH). Some classifications (e.g., CATH) also apply these pairwise methods to preliminary clustering of closely related multidomain structures before selecting structures from each multidomain sequence family identified for domain boundary recognition. Approximately 60% of domain structures deposited in the PDB over the last two years could be recognized using BLAST.

In CATH release 2.5.1, around 4000 families clustered at 35% sequence identity are currently recognized by these techniques. In the current SCOP database, release 1.65, close relatives have been clustered into 2327 families provided they share common functional properties. More remote homologs are then found by applying profile or HMM-based technologies (e.g., PSI-BLAST, SAM-T99). Currently, approximately 15–20% of newly deposited structures are classified using these approaches.

Finally, structure comparison methods are used to recognize very remote homologs and those proteins that share structural similarity but for which there is no other evidence of any evolutionary relationship. These structures, whose similarity may reflect convergence to an energetically or kinetically favored fold, are described as analogous structures and are discussed further below. In order to clearly distinguish homologs from analogs, it is often necessary to perform extensive manual validation of matches suggested by the structure comparison methods unless very highly significant scores are obtained. Usually, this analysis is done by searching the literature for evidence of common functional traits or visually inspecting the structures for rare structural motifs.

Various automatic methods for homolog validation have also been attempted. Russell and co-workers developed a method on the basis of Murzin's approach to classifying very remote homologs in the SCOP database, through identification of rare structural motifs conserved during evolution (Stark *et al*., 2003). Alternatively, Holm and co-workers have designed a neural network method that combines information on structure similarity, sequence similarity, and functional keywords (Dietmann and Holm, 2001). However, none of these approaches are completely reliable and therefore some degree of manual checking is generally performed for very remote homologs.

For the CATH database, once fold group and homologous superfamily have been assigned, architectures are assigned by manual inspection of structures. Subsequently, CATH employs an automated approach for explicitly defining protein class (Michie *et al*., 1996). This method calculates the percentage of residues in α-helical or β-strand conformations. It also takes account of the nature of secondary structure packing. Other resources do not explicitly assign class or, as in the case of SCOP, assign it by manual inspection.

7.1. Databases of structural neighbors

There are a number of on-line resources that provide lists of structural relatives for a given protein domain, rather than explicit classifications. FSSP (EBI), MMDB (NCBI), and the PDB (RCSB) do not generate protein families, but instead produce lists of structural neighbors for a given query sequence. FSSP provides a search tool that exploits the DALI algorithm to find structural relatives. Although a high structural similarity suggests homology, it is up to the user to decide how closely other domains are linked by evolution.

The MMDB exploits the vector-based VAST algorithm to automatically find similar structures within the PDB. It provides alignments annotated with automatic domain assignments and graphical structural superposition. The PDB resource itself makes use of the CE program to search for structural neighbors automatically. Again, it is up to the user to further group these into individual protein families.

Most of these resources use Z-scores to provide a measure of the significance for any structural match. Usually a value above 3 or 4 is a good indication of homology.

8. Analysis of protein structural families

Classifying proteins into families permits a more profound analysis of the mechanisms of evolution, such as identifying structural variations in the active sites of paralogs that have evolved to enable different substrates to bind. Analysis of structural families can also give insight into the biophysics of protein structure, such as secondary structure packing and favored topologies. In most families, we observe a highly conserved structural core, although in some families this is highly embellished to confer different enzymatic functions and protein–protein interaction partners (see a review by Orengo *et al*., 2001 and Todd *et al*., 2001).

It is important to remember that at present, transmembrane proteins are massively underrepresented in the PDB because they are difficult to crystallize and too large to be solved in solution by NMR. These proteins are hugely important in drug metabolism and it remains an experimental challenge to resolve the structure of these proteins. Once solved, they will provide valuable insight into how proteins have evolved differently to exploit the hydrophobic environment of cell membranes as opposed to the aqueous environment inhabited by most globular proteins.

Several groups have postulated that there are actually a limited number of superfamilies in nature, totaling only a few thousand (Chothia, 1992; Coulson and Moult, 2002, see Lee *et al*., 2003 for a review). With this in mind, the recent structural genomics initiatives aim to solve representative structures for all known protein families in the genomes. This will fill an important gap in our knowledge of evolution and the relationship between protein structure and function. Further structural representatives may allow currently distinct families in the sequence-based resources (e.g., Pfam) to be merged into superfamilies.

Several groups have shown that 50–60% of genes in completed genomes can currently be completely or partially assigned to fewer than 1500 structural superfamilies, using sensitive profile-based methods and HMMs (Gough *et al*., 2001, see Lee *et al*., 2003 for a review). This proportion increases to 70% if more powerful threading-based technologies are applied (McGuffin *et al*., 2004). From current analyses of the number of protein families identified in completed genomes (30 000–60 000 (see Lee *et al*., 2003 for a review)) this leaves many families to be structurally characterized. However, many of these families tend to be very small and specific to the organism or kingdom. They may comprise paralogs of common structural families that have acquired new and specific functions and have therefore diverged beyond the limit of sensitivity of sequence-based methods.

Extreme sequence divergence in paralogous genes may also explain the existence of analogous structures in some of the very highly populated fold groups in the structural classifications. For example, in CATH, some 55 fold groups comprise three or more different homologous superfamilies. This trend was first observed nearly a decade ago when the term "superfolds" was coined to characterize these highly recurrent folds (Chothia, 1992; Orengo *et al*., 1994). Currently in CATH, members of these fold groups comprise nearly one-third of all nonredundant (<35% sequence identity) domain structures. Although the diverse superfamilies observed within these fold groups may represent remote paralogs that have acquired new functions thereby removing some of the most important constraints on sequence conservation, they may also represent energetically favored folding arrangements.

It is reasonable to suppose that there are chemical–physical constraints on the ways in which proteins fold to optimize hydrophobic packing of core residues. This may also explain the preponderance of certain types of regular architecture. The most symmetric architectures in the CATH database (α-bundle, β-barrels, $\alpha\beta$-barrels, β-sandwiches and $\alpha\beta$-sandwiches) comprise nearly 60% of all nonredundant domains in CATH. Similarly, Shaknovitch and co-workers have shown that there are some folds in the database that are intrinsically able to support a much more diverse repertoire of sequences (Deeds *et al*., 2003).

Given the fact that we cannot obtain all the intermediate sequences arising during evolution of these popular folds, it is difficult to determine whether these structural

similarities represent divergence from a common ancestor or convergence to an energetically or kinetically favored fold.

Short Specialist Review

InterPro

Nicola J. Mulder and Rolf Apweiler
European Bioinformatics Institute, Cambridge, UK

1. Introduction

With the increasing availability of raw genome sequence data, the need for tools for protein functional annotation by automatic methods has arisen. The gap between the number of characterized and raw protein sequences in the public databases is widening, making it difficult to extract biological value from the vast quantity of new sequences. This has led to the emergence of protein signatures, which provide distinct advantages over the traditional sequence similarity methods of protein functional classification. There are different ways of deriving protein signatures (descriptive entities for a protein family, domain, or functional site), including regular expressions, profiles, or hidden Markov models (HMMs). PROSITE (Hulo *et al*., 2006) uses regular expressions and profiles, PRINTS (Attwood *et al*., 2003) uses an adaptation of profiles called *fingerprints*, and HMMs form the basis for Pfam (Finn *et al*., 2006), SMART (Letunic *et al*., 2006), TIGRFAMs (Haft *et al*., 2003), PIRSF (Wu *et al*., 2004), SUPERFAMILY (Madera *et al*., 2004), Gene3D (Yeats *et al*., 2006), and PANTHER (Mi *et al*., 2005). ProDom (Bru *et al*., 2005), on the other hand, uses sequence clustering to generate protein families. These are the major protein signature databases available, and while each of these is useful in its own right, the databases are far more effective when unified into a single resource. InterPro (Mulder *et al*., 2005) was created using these databases, as the value in uniting the efforts to provide a "one stop shop" for protein signature analysis was recognized.

2. Integration of signatures

All PRINTS fingerprints, PROSITE patterns and profiles, ProDom domains, and Pfam, SMART, TIGRFAMs, PIRSF, SUPERFAMILY, Gene3D, and PANTHER HMMs that identify the same protein family or domain within a set of protein sequences are grouped together in a single InterPro entry. The criteria for grouping are that signatures should overlap in position on the sequence and significantly in the proteins matched. Where one signature identifies a subset of proteins found by another signature, these are put into separate InterPro entries and relationships are inserted between these entries. Two types of relationships can exist between

InterPro entries: the parent/child and contains/found in relationships. Parent/child relationships are used to describe a common ancestry between entries, or where one entry represents a subfamily of another, whereas the contains/found in relationship refers to the domain composition.

3. Content of an InterPro entry

Each entry contains one or more signatures from the individual member databases that describe the same group of proteins. All entries contain a list of matches against all proteins in UniProtKB (Wu *et al*., 2006) and annotation regarding the protein family/domain.

3.1. Protein matches

Protein matches are calculated using the InterProScan (Quevillon *et al*., 2005) software package, which is a combination of the search methods of the individual databases. The match lists may be viewed in tabular and different graphical formats. The table lists the protein accession numbers and the positions in the amino acid sequence where each signature from that InterPro entry hits. In the detailed graphical view, the sequence is split into lines for each hit by a unique signature and the bars are color coded by member database. The proteins can also be viewed graphically in an overview, which splits the protein sequence into different lines for each InterPro entry matched. Where structures are available for proteins, there is a link from the graphical view to the corresponding Protein Data Bank (PDB) structures and a separate line in the display showing the SCOP (Andreeva *et al*., 2004) and/or CATH (Orengo *et al*., 2003) curated matches on the sequence as white striped bars. Where the structures have not been solved but can be modeled by MODBASE (Pieper *et al*., 2004) or SWISS-MODEL (Kopp and Schwede, 2006), these are displayed as yellow and white or red and white striped bars, respectively. Protein matches are also now available for different splice variants, which are displayed together with matches for the master sequence.

A new protein match view is the InterPro Domain Architectures (IDAs) view, which summarizes the InterPro matches as oval beads along the sequence. All proteins with the same sequence of InterPro matches are shown once, with the number of proteins sharing this architecture displayed on the left. The IDA view as well as the table and detailed views can be displayed simultaneously for a protein sequence by inserting the UniProtKB protein accession number in the search box and selecting “Find protein matches” (Figure 1). In the protein match views, the user can also select protein sets by the protein or InterPro accession number(s), whether they have solved structures or splice variants, or by taxonomy. Results can be displayed in any of the above formats.

3.2. InterPro annotation

InterPro entries provide annotation in the form of a name, a short name, and an abstract describing the proteins in question. The abstracts provide the bulk of the

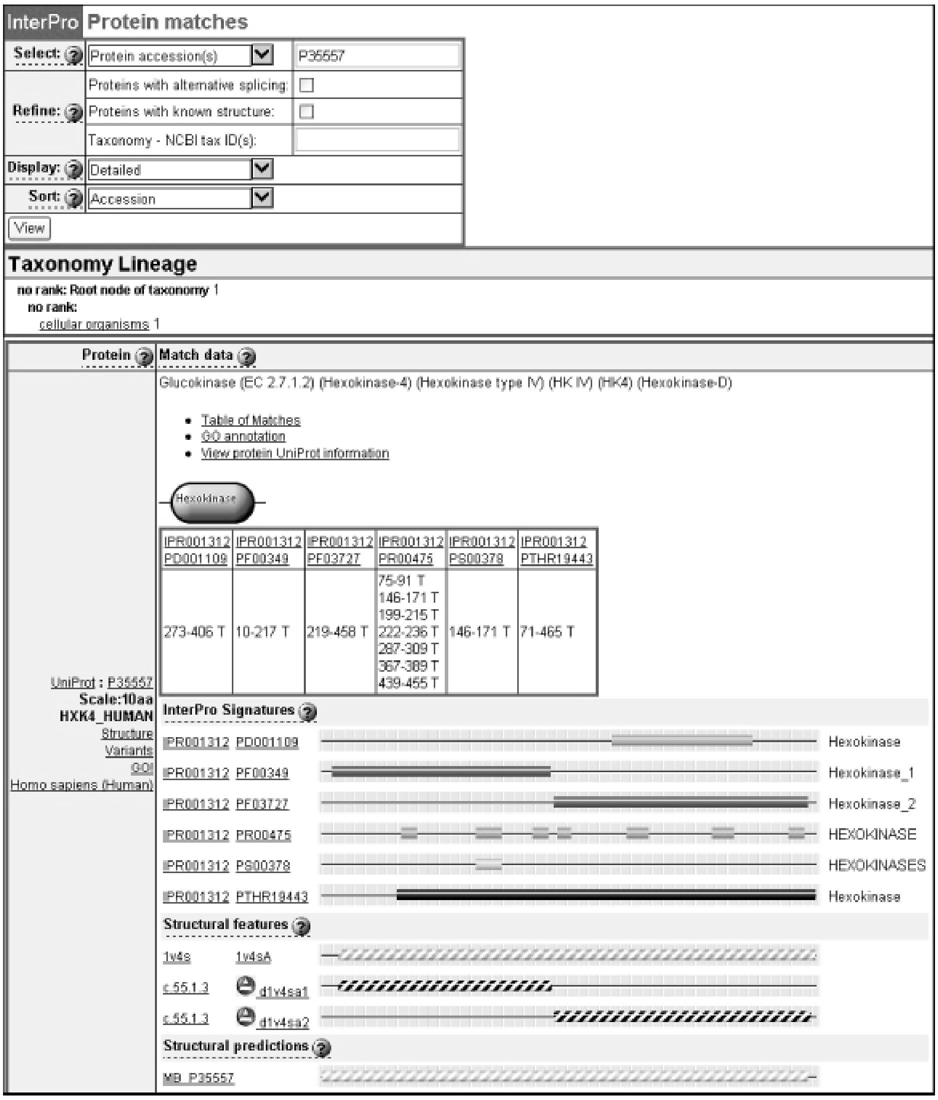

Figure 1 Example of InterPro search results for UniProtKB protein P35557, the human Glucokinase protein. This view shows the matches for this protein in various formats, including the domain architecture, table, and detailed views. The new searching options are shown at the top of the figure, where one can search by InterPro accession, protein accession, or architecture code; filter results by taxonomy ID, proteins with known structure, or splice variants; and display the output in different formats with user-selected ordering

annotation and cite the relevant publications. Additional annotation is in the form of cross-references to specialized databases, such as the MEROPS peptidase database, BLOCKS, and more recently, the IntAct protein–protein interaction database. Links to the PDB, SCOP and CATH structural databases are provided when proteins matching the entry have solved structures. A taxonomy field in each InterPro entry

aims to provide an indication of the taxonomic range of proteins matched by the entry.

Mapping of InterPro entries to GO (Gene Ontology) terms (Harris *et al*., 2004) provides a means for the automatic mapping of the proteins matched to the same GO terms. Entries are mapped to the relevant terms at the most appropriate level in the GO hierarchy when the characterized proteins in the match list share a common molecular function or biological process, or perform their function in the same cellular component (these are the three divisions in GO). The terms are then assumed to apply to all the other proteins matched. These InterPro2GO mappings are the largest providers of GO annotations to proteins.

4. Data access

InterPro is implemented in an Oracle relational database, and is available for text or sequence searches via the web. A simple text search allows the user to query InterPro entries or protein matches, but more complex queries can be performed through sequence retrieval system (SRS) (**http://srs.ebi.ac.uk/**). Query protein or DNA sequences can be submitted to InterProScan interactively or via email. A DNA sequence will be translated in all six frames before submission to InterProScan. If confidentiality or bulk searches are required, users may download a Perl stand-alone InterProScan package for running locally. The results will give an indication of what family the unknown protein belongs to, its domain composition, and potential GO annotations, where available. For more information, the user can read about related proteins or the protein family in the annotation of the InterPro entries it hits.

5. Discussion

Genome sequences of a number of different organisms of different kingdoms of life are currently being sequenced or have already been sequenced. This has a potentially large impact on biologists around the globe working on these various organisms. Instead of seeing the small picture, they are now able to get a bigger picture of where their gene of interest fits into the whole system. In other words, context information, like biological pathways, should be more accessible, since the sequences of all players in the pathways are available. However, this is only possible if those players have been identified and classified. Methods of sequence clustering and protein signatures are now well established and are very useful in the prediction of protein function. Each is different though, so their unification into InterPro and the value-added annotation in InterPro entries provide a powerful resource for sequence analysis and genome annotation. InterPro has already been used for the annotation of a multitude of complete genomes, including that of human (The International Human Genome Consortium, 2001) and mouse (Kawaji *et al*., 2002). It is used for large-scale automatic annotation of TrEMBL, and is continually showing its worth in new applications.

Short Specialist Review

Functionally and structurally relevant residues in PROSITE motif descriptors

Christian J. A. Sigrist, Edouard De Castro, Petra S. Langendijk-Genevaux, Virginie Le Saux, Amos Bairoch and Nicolas Hulo
University of Geneva, Geneva, Switzerland

1. Introduction

PROSITE is an annotated collection of biologically meaningful motif descriptors dedicated to the identification of protein families and domains (*see* Article 91, **Classification of proteins by sequence signatures**, Volume 6). Its current release 18.43 (January 4, 2004) contains 1311 documentation entries describing 1775 motif descriptors, which are either patterns or profiles (Hulo *et al*., 2004; Sigrist *et al*., 2002). Both are derived from multiple alignments of homologous sequences, giving them the notable advantage of identifying distant relationships between sequences that would have passed unnoticed based solely on pairwise sequence alignment.

PROSITE is also a member database of InterPro (*see* Article 83, **InterPro**, Volume 6) (Mulder *et al*., 2003) and a main contributor to the InterPro annotation. More information on PROSITE is available at **http://www.expasy.org/prosite**.

2. PROSITE patterns

The first motif descriptors used by PROSITE were *regular expressions* or *patterns*. Patterns describe a group of amino acids that constitute a usually short, but characteristic motif that constitutes the signature of a function, a posttranslational modification, a domain, or a protein family. These motifs arise because specific region(s) of a protein, which are important, for example, for their binding properties or their enzymatic activity, are conserved in both structure and sequence. In a pattern, the motif is reduced to a consensus expression in which all but the most significant residue information is discarded. PROSITE patterns are qualitative, they either match or they do not. If there is a mismatch at any position, the pattern will not match, even though the mismatch is a conservative, biologically feasible substitution.

Despite their limitations, patterns are still very popular since:

- They are easy to formulate and to use.
- The scan of a protein database with patterns can be performed in reasonable time on any computer.
- They are well designed for the detection of biologically meaningful sites and the residues playing a structural or functional role are easily identifiable. This quality of patterns is further strengthened by the information contained in the */SITE* qualifier of the CC lines, which indicates, among other features, active sites, disulfide bonds, and/or metal and other binding sites in a PROSITE pattern.

3. PROSITE profiles

Recently, patterns have tended to be replaced with the more sophisticated *generalized profiles* (or *weight matrices*), which show an enhanced sensitivity when compared to patterns and are able to detect highly divergent families or domains with only a few well-conserved positions. Profiles also characterize protein domains over their entire length, not just the most conserved parts of them.

The generalized profiles (Bucher *et al*., 1996; Bucher and Bairoch, 1994; Hofmann, 2003) used in PROSITE are quantitative motif descriptors providing a scoring table of position-specific amino acid weights and gap costs. The automatic procedure used for deriving profiles from multiple alignments is capable of assigning appropriate weights to residues that have not yet been observed at a given alignment position, using the empirical knowledge about amino acid substitutability contained in a substitution matrix (Dayhoff *et al*., 1978; Henikoff and Henikoff, 1992) or methods involving hidden Markov modeling. The numerical weights of a profile are used to calculate a similarity score for any alignment between a profile and a sequence, or parts of a profile and a sequence. An alignment with a similarity score higher than or equal to a given cutoff value constitutes a match. This cutoff value is estimated by calibrating the profile against a randomized protein database (Pagni and Jongeneel, 2001; Sigrist *et al*., 2002). The normalization procedure used for PROSITE profiles makes the normalized scores independent of the database size, allowing comparison of scores from different scans. A mismatch at a highly conserved position can thus be accepted, provided that the rest of the sequence displays a sufficiently high level of similarity.

4. Functionally and/or structurally relevant residues in profiles

Although profiles generally cover domains or proteins over their entire length and hence make the identification of the biologically most relevant residues less obvious than with patterns, functionally and structurally important amino acids can be recovered from the alignment between the profile and the matched sequence, provided that their position in the profile is known. As a domain might have acquired different functions through substitutions of critical residues during

evolution, it is necessary, once these residues are identified, to check if they fulfill the condition expected for the functional and/or structural properties associated with the domain. If not, it means that the expected biological property is no longer associated with the domain or that residues at other positions in the sequence compensate for it. Hence, serine proteases of the trypsin type and haptoglobin share a structural domain whose catalytic residues are no longer present in the nonenzymatic haptoglobin (Kurosky *et al*., 1980) (see Figure 1). This example illustrates clearly that it is not sufficient to just know about the presence of a domain to make valid functional predictions, but that in most cases it is necessary to have information about particular residues to predict the biological function of a domain more accurately.

As PROSITE aims to be an annotated database consisting of biologically significant sites, patterns, and profiles that help reliably identify to which known protein family a new sequence belongs, we decided to use information about functionally and/or structurally meaningful residues of a profile to make more specific assumptions. Whereas positions of biologically relevant residues are stored together with the regular expression (CC \SITE lines of the pattern), we have created a new section of PROSITE (ProRule) to store the position of interesting residues contained in profiles. ProRule contains the position in the profile of residues potentially involved in disulfide bonds, catalytic activity, phosphorylation, prosthetic group attachment (heme, pyridoxal-phosphate, biotin, etc.), or metal, protein, or molecule (ADP/ATP, GDP/GTP, calcium, DNA, etc.) binding, or forming a transmembrane region. For each of these amino acids at potentially interesting positions, ProRule also contains the condition(s) the residue must fulfill to play its structural and/or functional role. These conditions can, in some cases, be quite complex in order to provide the user with the most precise and relevant information possible. For example, as the catalytic center of the trypsin-type serine protease domain is formed by a triad of residues, we consider that the group of three amino acids must be present to make a confident prediction about the function of the domain. For the prediction of disulfide bridges, conditions have to be even more complex as it is known that disulfide bridges are not always invariant among homologous domains: conserved cysteine residues can exhibit different disulfide bond patterns from one protein type to the other (Calvete *et al*., 2000; Chong *et al*., 2002). In some instances, the situation is so complex that it is not possible to reduce the biological diversity to a set of conditions predicting unambiguously which bond will be made, and no rules can be made.

From the positional and conditional information contained in the rules, residues with a potential functional and/or structural function can be retrieved in a new sequence from its alignment with the profile, and their agreement with the expected function checked, providing additional useful information to the user. For the 455 profiles available in the current release of PROSITE, 94 ProRules (∼21%) contain information about functionally and/or structurally critical amino acids.

PROSITE users analyzing their sequences through the ScanProsite web page (**http://www.expasy.org/tools/scanprosite/**) can benefit from the additional information contained in ProRule and get not only the domain boundaries but also the position and potential function of critical residues that might be found in the

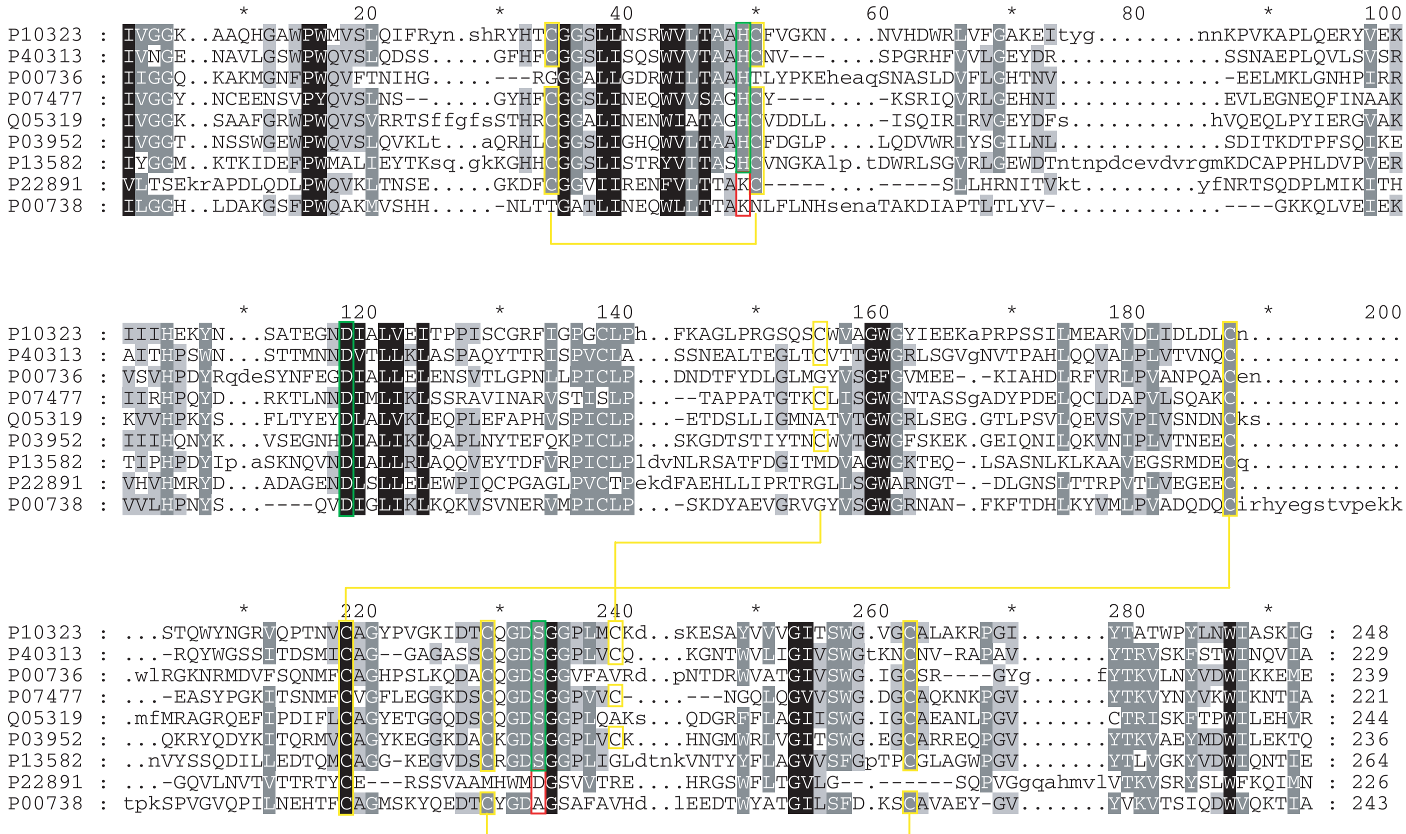

Figure 1 Multiple alignment of the trypsin-type serine protease domain (PS50240) of human acrosin (P10323), chymotrypsin-like protease CTRL-1 (P40313), complement C1r component (P00736), trypsin I (P07477), plasma kallikrein (P03952), vitamin K–dependent protein Z (P22891) and haptoglobin (P00738), and drosophila serine proteinases stubble (Q05319) and easter (P13582). Some proteins lack cysteine residues involved in disulfide bonds and the vitamin K–dependent protein Z and haptoglobin have lost two of the essential catalytic residues (histidine and serine) and have no enzymatic activity. The residues from the catalytic triad are shown in green boxes if they are compatible with the catalytic activity and in red boxes if not. The cysteines known to be involved in disulfide bonds (yellow lines) are in yellow boxes. The accession numbers (AC) correspond to records in the Swiss-Prot section (Boeckmann *et al*., 2003) of the UniProt Knowledgebase (Apweiler *et al*., 2004)

profiles. This supplementary service should facilitate protein analysis by making functional prediction more accurate.

Short Specialist Review

The PRINTS protein fingerprint database: functional and evolutionary applications

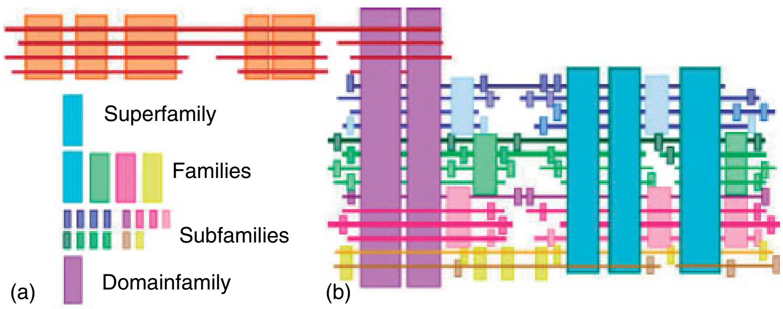
Teresa K. Attwood and Alexander L. Mitchell

University of Manchester, Manchester, UK

European Bioinformatics Institute, Cambridge, UK

Anna Gaulton, Georgina Moulton and Lydia Tabernero

University of Manchester, Manchester, UK



1. Introduction

The PRINTS database houses a collection of protein sequence "fingerprints" that, by encapsulating the conserved features of known family members, may be used to assign functional and structural attributes to uncharacterized sequences. As with several other pattern-recognition approaches, fingerprinting exploits multiple sequence alignments to derive its familial signatures. When building alignments, insertions are often required at particular positions to bring equivalent parts of adjacent sequences into register. As a result, islands of conservation tend to emerge from a backdrop of mutational change. These conserved regions or "motifs" (typically $<15-20$ residues in length) tend to correspond to the core structural or functional elements of the protein. Taken together, these motifs may therefore provide a signature for the aligned family. In 1990, this observation prompted the creation of the PRINTS database of diagnostic fingerprints for use in protein sequence classification and characterization.

2. Distinguishing features of fingerprinting

The fingerprinting method involves manual creation of a seed alignment, followed by identification and excision of conserved motifs (up to a maximum of 15 motifs, of maximum length 30 residues). The motifs are translated into frequency matrices (no mutation or other similarity data are used to weight the results)

and searched against the source database, a fragmentless version of the Swiss-Prot/TrEMBL component of UniProt (Apweiler *et al*., 2004). Fingerprint diagnostic performance is enhanced by iterative scanning; the motifs therefore mature with each database pass, as more sequences are matched and assimilated into the process. When the iterative process has converged, the fingerprints are annotated manually with biological information, literature, database cross references, and so on, before accession to the database. The fingerprinting technique departs from other pattern-matching methods by readily allowing the creation of signatures at the domain-, superfamily-, family-, and subfamily-specific levels (Figure 1). This degree of resolution is possible because the manual approach allows us to focus not only on regions of shared similarity (such as those that characterize superfamilies) but also on regions of difference. (such as those that resolve subfamilies from closely related siblings within a family, or those that distinguish

Figure 1 Resolving domain-, super- and subfamily relationships. At the top of the figure, gapped alignments of two theoretical families are represented: (a) a gene family and (b) a typical superfamily. Motifs are denoted by colored rectangles. Members of the superfamily are likely to share a similar overall structure and function; its constituent families (blue, green, pink, and yellow) have more specific functions; and their subfamilies (shades of each color) have highly specialized functions closely related to the family to which they belong. At the N-terminus of the superfamily lies a genetically mobile domain, or module (the purple motifs), a copy of which also lies at the C-terminus of the gene family. While the domain has the same overall structure and function in both biological contexts, the gene family and superfamily are otherwise unrelated. All families containing the domain collectively comprise a domain family. Fingerprint analysis of Swiss-Prot entry THRB HUMAN (accession number P00734), human prothrombin, is shown in (c). One family-level fingerprint is matched, PROTHROMBIN (PR01505), and one superfamily-level fingerprint, CHYMOTRYPSIN (PR00722). This suggests that the protein is prothrombin and belongs to the peptidase family S1A, the chymotrypsin serine proteases. The sequence also matches two domain signatures: KRINGLE (PR00018) and GLABLOOD (PR00001); these modules are commonly found in proteins involved in blood coagulation

families from their parent superfamilies). This is important because it is the subtle differences between close relatives that largely determine their functional specificities. This hierarchical approach has been used to analyze a range of proteins, especially those of pharmaceutical interest – for example, to resolve G-protein-coupled receptor (GPCR) superfamilies into their constituent families and receptor subtypes (Attwood, 2001), and to finely classify a variety of channel proteins, transporters, and enzymes. Fingerprinting therefore provides a useful complement to the hidden Markov model and profile-based methods, which tend to specialize in the diagnosis of superfamilies or domains. The diagnostic potency of fingerprints derives primarily from the use of multiple motifs and the mutual context provided by motif neighbors – the more motifs a signature contains, the better able it is to identify distant relatives, even when parts of the signature are absent (*e.g.*, a sequence matching five of eight motifs may still be diagnosed as a true match, if the motifs are matched in the correct order, and the distances between them are consistent with those expected of true neighboring motifs). The method is thus sufficiently robust to tolerate mismatches at the level both of individual residues within motifs, and of motifs within complete signatures (Attwood, 2002); it is therefore more flexible and powerful than single-motif approaches.

3. Distinguishing features of PRINTS

PRINTS' motifs are stored in the form of ungapped, local alignments. This allows different implementations to be established with alternative scoring methods. Thus, a Blocks-format version of the database that exploits Blocks-scoring methods is available at the Fred Hutchinson Cancer Research Center (Henikoff *et al*., 2000). In addition, the eMOTIF and eMATRIX resources at Stanford derive permissive regular expressions (Huang and Brutlag, 2001) and position-specific scoring matrices (Wu *et al*., 2000) from PRINTS' multiply aligned motifs, offering different levels of stringency from which to infer the significance of matches. Derivative databases are useful as they provide different perspectives on the same data: they allow validation of results where there are equivalent matches in more than one resource and they offer the chance to make diagnoses that may have been missed by the original implementation.

Another important feature of PRINTS is that it is one of the few signature databases that includes significant amounts of manually crafted annotation. The purpose of the annotation is both to provide background information on the gene or domain family being described and to rationalize the motifs in functional and structural terms. The annotation procedure is exhaustive and time consuming; consequently, PRINTS remains relatively small by comparison with other, largely automatically derived, signature databases. Overall, however, the precision of the results, coupled with the extent of its annotations, has justified the sacrifice of speed, and has set the database apart from the growing number of resources that contain little, if any, annotation. In this respect, PRINTS adopts a similar philosophy to PROSITE (described in Article 84, **Functionally and structurally relevant residues in PROSITE motif descriptors**, Volume 6) (Falquet *et al*.,

2002) and, in 1992, the database curators agreed to collaborate in creating a composite resource – this goal was eventually realized in 1999 with the first release of InterPro (*see* Article 83, **InterPro**, Volume 6) (Mulder *et al*., 2003), which, by that time, also included profiles, Pfam (described in Article 86, **Pfam: the protein families database**, Volume 6) (Bateman *et al*., 2002) and ProDom (Servant *et al*., 2002).

4. An automatic supplement, prePRINTS

To address its limited size, we developed an automatic supplement, termed prePRINTS (Attwood *et al*., 2003). This uses ProDom clusters as seed alignments; motif detection and iterative scanning are performed automatically, and the results annotated using the PRECIS annotation tool (Mitchell *et al*., 2003; (**http://umber.sbs.man.ac.uk/cgi-bin/dbbrowser/precis/precis.cgi**). prePRINTS is a valuable extra source of fingerprints, serving as an "incubator", where entries are manually refined before accession to PRINTS.

5. Functional and evolutionary applications

In addition to its role in classifying protein sequences into families and providing source data for the Blocks, eMOTIF, eMATRIX, and InterPro databases, PRINTS has been used in a number of functional and evolutionary studies. For example, its extensive collection of hierarchical K+ channel fingerprints has been used to mine mammalian, *Caenorhabditis elegans*, and *Drosophila melanogaster* proteomes, and the identified proteins classified according to the seven known families. Subsequent phylogenetic analyses allowed identification of orthologous relationships and shed light on likely underpinning evolutionary events, such as gene duplications and gene losses (Moulton *et al*., 2003). The implicit evolutionary relationships within the PRINTS hierarchy have thus been exploited, and have been explicitly expressed, by using phylogenetic methods.

In another analysis, PRINTS' vast repertoire of GPCR fingerprints has been used to investigate the structural and functional relationships of superfamily-, family-, and subfamily-level motifs. The study revealed that while some family- and subfamily motifs map onto residues and regions that participate in ligand binding (Figure 2) and G-protein coupling, others contain regions that are involved in protein–protein interactions and receptor dimerization (Figure 3), suggesting that these fingerprints could be used to predict the locations of ligand-binding sites and other functional features in as yet uncharacterized receptor families.

More recently, fingerprints for two mitogen-activated protein kinase (MAPK) phosphatase subfamilies (tyrosine specific and dual specificity) were used in genome-wide screens, identifying more than 80 MAPK phosphatase domains, several from partial sequences or nonannotated proteins. One of the predicted orthologs from *Xenopus* was confirmed experimentally to bind to ERK1/2, suggesting a role in MAPK signaling. Structural analysis of the fingerprints using the 3D structure of MAPK phosphatases as template revealed motifs

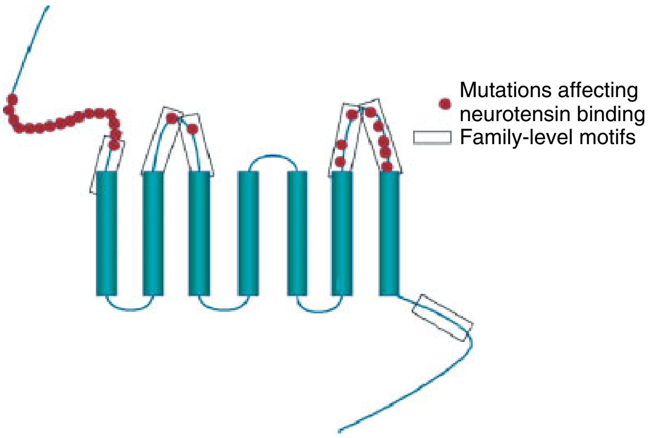

Figure 2 Schematic drawing of the neurotensin receptor, with family motifs mapped (rectangles), together with positions of mutations known to affect neurotensin binding (red circles). Most motifs contain residues important in ligand binding

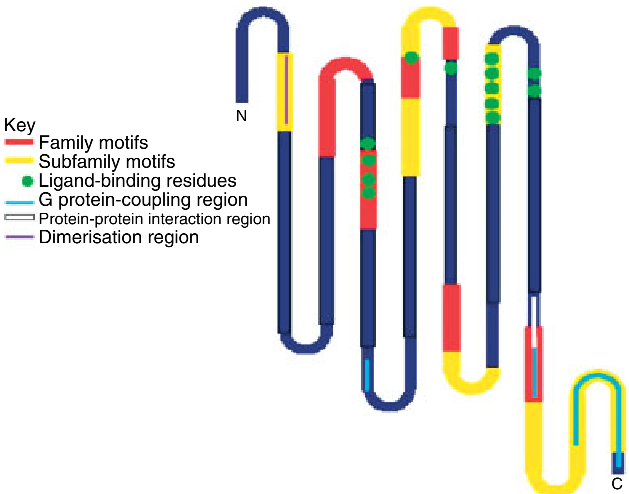

Figure 3 Schematic drawing of the bradykinin receptor, with family- (red) and subfamily (yellow) motifs mapped, together with positions of residues involved in ligand binding (green circles), G-protein coupling (light blue bars), receptor dimerization (purple bar), and other protein–protein interactions (white bar)

in the N-terminal non-catalytic regions that coincided with reported MAPK binding sites, and other motifs in the catalytic phosphatase domain suggestive of putative allosteric sites for modulation of protein–protein interactions (Figure 4). The fingerprints have therefore been useful not only for rapid annotation and

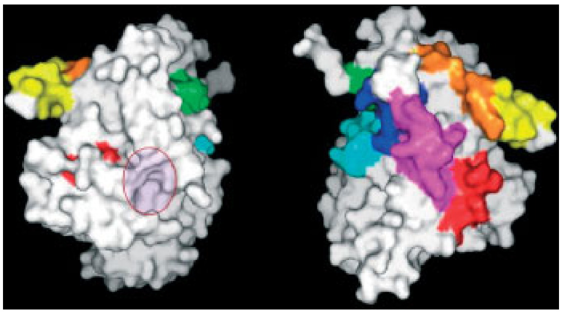

Figure 4 Surface representation of the catalytic domains of hematopoietic protein-tyrosine phosphatase; the motifs in the fingerprint are colored on the surfaces to highlight their clustering. The left-hand image shows the front view of the protein, the active site marked with a translucent oval; the right-hand image shows the back view, where the fingerprint motifs can be seen to form a continuous exposed surface, suggestive of an interaction surface

classification of MAPK phosphatase domains, but also for novel identification of putative functional motifs, providing a framework for future experimental studies.

6. Availability

Maintained at the University of Manchester, PRINTS 38.0 and prePRINTS 2.0, containing ~11 500 and 1510 motifs (1900 and 380 fingerprints) respectively, are available for searching at **http://www.bioinf.man.ac.uk/dbbrowser/PRINTS/** and **http://www.bioinf.man.ac.uk/dbbrowser/prePRINTS/**.

7. Conclusion

The PRINTS protein fingerprint database provides a potent means of classifying uncharacterized sequences at the domain-, super-, and subfamily levels and also provides a rich source of manually crafted annotation. These features set it apart from the growing number of signature databases, many of which offer little or no annotation and tend to focus on the diagnosis of domain families and superfamilies. In addition to its utility as a sequence analysis tool, the resource also has value both in shedding light on evolutionary relationships and in predicting functional sites in complex gene families.

Pfam: the protein families database

Robert D. Finn
Wellcome Trust Sanger Institute, Cambridge, UK

1. Introduction

Over a million protein sequences have been deposited in the UniProt sequence database (Apweiler *et al*., 2004). The number of new sequences deposited shows no signs of abating. Thus, protein sequence analysis may seem like an endless task. However, the majority of protein sequences appear to fall into a few thousand protein families (Chothia, 1992). Therefore, if we can place new sequences into existing families, we can make our task simpler. Very often, these protein families are representative of proteins at the domain level. Domains are discrete structural units that are frequently found in different molecular contexts. Different combinations of domains give rise to functional diversity (Vogel *et al*., 2004), which includes their ability to form different protein interactions.

2. The Pfam database

Pfam is a database of protein domain families (Bateman *et al*., 2004). Each family is represented by multiple sequence alignments and profile hidden Markov models (HMMs). In addition, each family has associated annotation, literature references, and links to other databases. The entries in Pfam are freely available via the web and in flatfile format (Pfam is available in Europe at **http://www.sanger.ac.uk/Software/Pfam/** (United Kingdom), **http://www.cgb.ki.se/Pfam/** (Sweden), and **http://pfam.jouy.inra.fr/** (France), and in the United States at **http://pfam.wustl.edu/**). Pfam is a founding member database of InterPro (*see* Article 83, **InterPro**, Volume 6) and, therefore, also available via the InterPro site at **http://ebi.ac.uk/interpro**.

The use of Pfam by molecular biologists as a protein information resource and analysis tool is widespread. The multiple sequence alignments around which Pfam families are built are important for understanding both protein structure and function. The alignments are also the basis for techniques such as secondary structure prediction, fold recognition, and phylogenetic analysis and can guide mutation design. In addition to the identification of domains in novel protein sequences,

Pfam can be used in conjunction with the Wise2 package to predict genes and annotate genomic DNA.

There are two multiple sequence alignments for each Pfam family; the seed alignment containing a manually curated set of representative members of the family and the full alignment that contains all detectable members in the sequence database. The underlying sequence database, called *Pfamseq*, is based on UniProt (Apweiler *et al*., 2004). An HMM is built from the seed alignment using the HMMer2 software package (**http://hmmer.wustl.edu/**) and used to search the Pfamseq database. All matches (scoring above a curated set of thresholds) are aligned against the HMM to make the full alignment. Full alignments can be large, with the top 20 families now each containing over 7000 sequences. For example, the largest full alignment in Pfam (the HIV GP120 glycoprotein) has over 40 000 members, yet the seed alignment only has 24 representative members.

Pfam is designed to be both accurate and comprehensive (Sonnhammer *et al*., 1998). As such, the Pfam database is structured in two parts, referred to as *Pfam-A* and *Pfam-B* (Bateman *et al*., 2004; Sonnhammer *et al*., 1998). The Pfam-A entries are manually curated families with high-quality sequence alignments and annotations. At the time of writing, the latest release of Pfam (13.0) contains 7426 Pfam-A families. Seventy-four percent of all sequences in UniProt contain at least one match to Pfam-A, and these families cover approximately 53% of all residues in the protein databases. However, as Pfam aims to be comprehensive, the sequences not covered by Pfam-A families are clustered according to the PRODOM database (Servant *et al*., 2002), and are referred to as *Pfam-B entries* (see Pfam-B flatfile). The Pfam-B supplement contains ~90 000 small protein families of lower quality.

So why use a domain database? Traditional approaches to large-scale sequence annotation use a pairwise sequence comparison method such as BLAST (Altschul *et al*., 1990) to find similarity to proteins of known function (*see* Article 39, **IMPALA/RPS-BLAST/PSI-BLAST in protein sequence analysis**, Volume 7). Annotations are transferred from the protein of known function to the predicted protein. The pairwise similarity search does not give a clear indication of the domain structure of the proteins, and mistakes in annotation can result from not considering the domain organization of proteins. For example, a protein may be misannotated as an enzyme when the similarity is only to a regulatory domain.

3. Pfam proteome coverage

Pfam was originally designed to aid the annotation of the genomes, in particular the *Caenorhabditis elegans* genome. More recently, Pfam-based annotations have been applied to many genome projects, including human, mouse, and fly. The coverage of Pfam across the sequence database is high. An alternative measurement of coverage is the coverage of a proteome. Figure 1 shows graphically the results from Pfam/HMMer analysis on the proteomes from eight representative genomes: the eubacteria *Escherichia coli*, *Aquifex aeolicus*, *Streptomyces coelicolor*, the archaeon *Methanococcus jannaschii*, the yeast *Saccharomyces cerevisiae*, the nematode *Caenorhabditis elegans*, the fly *Drosophila melanogaster*, the plant *Arabidopsis thaliana*, and human *Homo sapiens*.

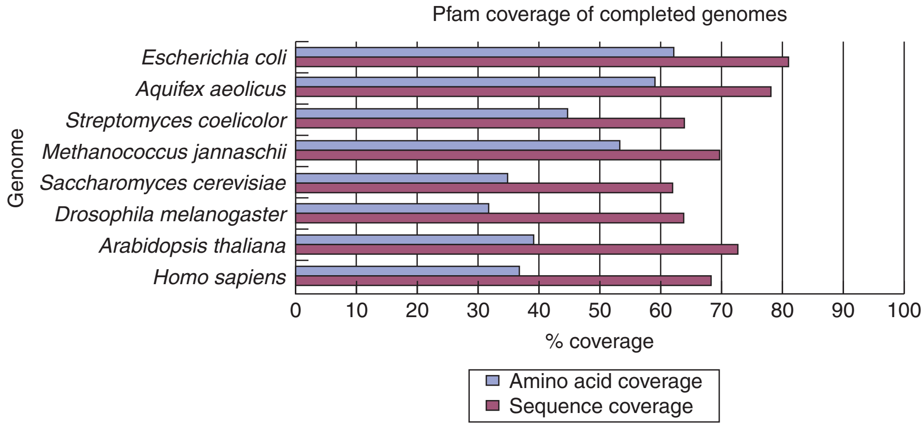

Figure 1 Pfam-A coverage of a representative selection of completed genomes, from all kingdoms of life. The per-residue coverage is indicated by the blue bars and the per-sequence coverage is indicated by the red bars

In the example proteomes, the sequence coverage by Pfam-A families is always greater than 60%, but in the case of *E. coli*, exceeds 80%. The amino acid coverage can be as low as 34.8% for yeast, yet as high as 62.2% in *E. coli.* Thus, Figure 1 shows that the genomic coverage by Pfam differs greatly.

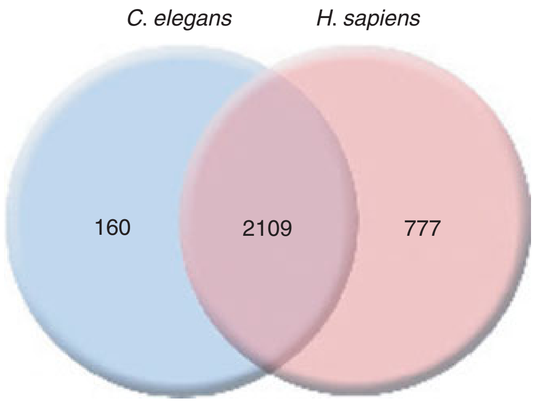
4. Genome comparisons

As more genomes become completed, it is interesting and informative to identify which protein families are specific to a particular genome and which families are common to genomes. Pfam readily allows such analyses to be performed. For example, if the protein families in human and the model organism *C. elegans* are compared, we find that there are 2109 families that are found in both organisms, 777 families that are specific to human, and 160 that are specific to *C. elegans* (see Figure 2). In the case of common domains, *C. elegans* may provide an appropriate model system for studying human proteins of interest. Similar analyses may be useful in identifying domains that are responsible for symbiosis in bacteria and drug targeting for intracellular pathogens.

Pfam is not only aimed at sequence and genome annotation. Pfam also contains functional information about the families, where available. For example, secondary structure, solvent accessibility, and active site information can be found in the alignments. Recently, a whole new resource has been made available for studying domain interactions, called *iPfam* (Finn *et al*., 2005) (**http://www.sanger.ac.uk/Software/Pfam/iPfam**).

5. Domain interactions

Large-scale protein interaction analyses indicate that the majority of proteins bind transiently or are part of large molecular complexes (Gavin *et al*., 2002).



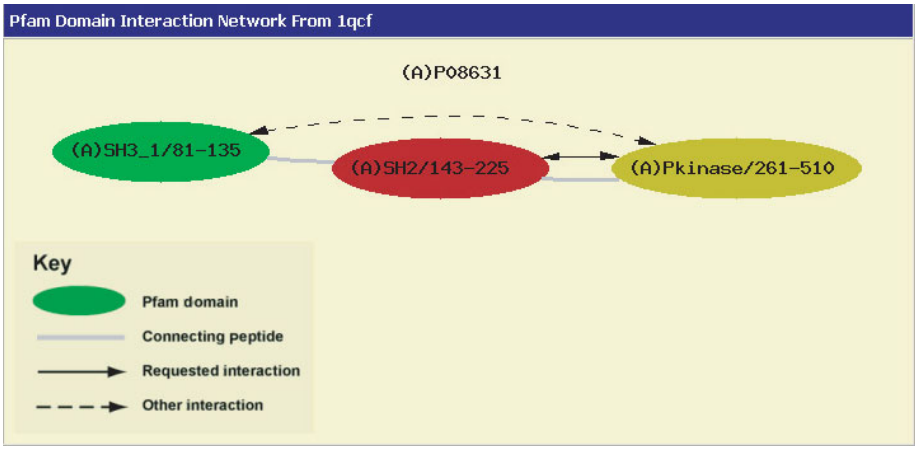


Figure 2 Comparison of domain distribution between *H. sapiens* (pink) and *C. elegans* (blue). The Venn diagram shows which families are in common between the two organisms (2109) and which families are specific to each organism. This data was produced from the search engine at **http://www.sanger.ac.uk/Software/Pfam/genome_dist.pl**

To understand protein interactions at a molecular level, information at the resolutions of domains, residues, and atoms are required. This sort of detailed interaction information is normally only found in the PDB database of protein structures. Approximately, one-third of the 7426 Pfam-A entries have one or more structural representatives. The *i*Pfam resource describes domain–domain interactions observed in known protein structure at the resolution of protein(s), domains, residues, and atoms. At the time of writing, there are over 2500 different domain–domain interactions described. Currently, the *i*Pfam data is laid out in two different ways. First, for a specific structure containing a domain–domain interaction. In this case, the structure, domains, and interactions are displayed as a 2D graph (Figure 3a). The interaction can be explored further at the residue- and atom-resolution levels, either as sequence or structure. The second way the data is presented in *i*Pfam allows the visualization of the conservation of domain–domain interactions between different examples of the same domain (Figure 3b). Such a display quickly allows the user to discern which residues are always found at a particular domain–domain interface and, when multiple domains are compared, whether interacting interfaces overlap.

6. Future prospects

Pfam continues to add new entries and review existing families to improve the coverage of sequence space. New strategies for building more comprehensive families are being developed. Web services allowing machine access to the data will be available shortly, to enable a more automated access to annotational and functional information contained within Pfam.

Short Specialist Review

The PIR SuperFamily (PIRSF) classification system

Winona C. Barker
National Biomedical Research Foundation, Washington DC, USA

Raja Mazumder, Anastasia N. Nikolskaya and Cathy H. Wu
Georgetown University Medical Center, Washington DC, USA

1. Introduction

The Protein Information Resource (PIR) supports genomic and proteomic research by providing protein databases and analysis tools freely accessible to the scientific community (Wu *et al*., 2003a). The PIR-International Protein Sequence Database of functionally annotated protein sequences grew out of the *Atlas of Protein Sequence and Structure* edited by Dayhoff (1965–1978). The previously independent protein sequence database activities of PIR, the European Bioinformatics Institute, and the Swiss Institute of Bioinformatics are now unified to provide UniProt, the Universal Protein Resource (Apweiler *et al*., 2004), as a central resource of protein sequence and function.

The major purpose of the PIRSF (Protein Information Resource SuperFamily) classification system is to facilitate sensible propagation and standardization of protein annotation, specifically in the UniProt database. Basing classification on full-length proteins allows annotation of biological functions, biochemical activities, and sequence features that are family specific. In contrast, the domain architecture of a protein provides insight into general functional and structural properties, as well as into complex evolutionary mechanisms. Thus, the PIRSF can be used by the scientific community as a tool for such diverse activities as genome annotation, study of evolutionary mechanisms, comparative genomic studies, choosing of candidate proteins for structural genomics projects, and analysis of proteomic expression data.

2. PIRSF concept and properties

The protein superfamily concept articulated by Dayhoff (1976) was the first classification based on sequence similarity, where sequences were categorized into

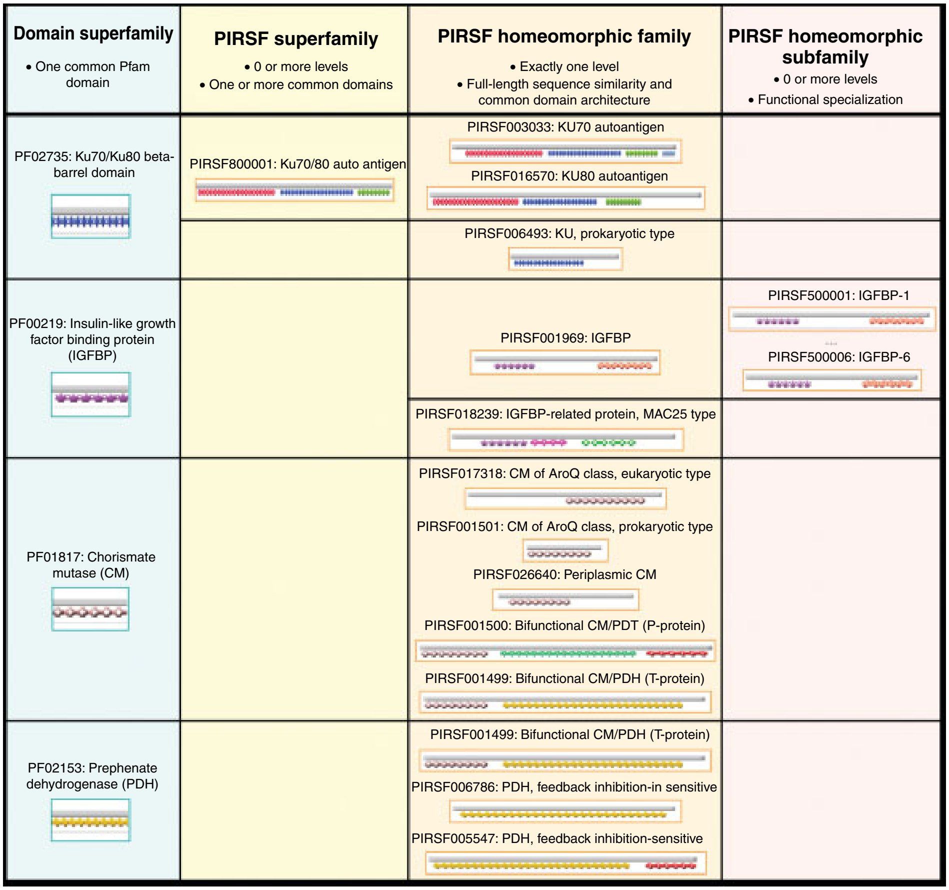

Figure 1 PIRSF classification system based on evolutionary relationship of full-length proteins

superfamilies and further subdivided into closely related families, very closely related subfamilies, and nearly identical entries using different percent identity thresholds. This hierarchical structure was challenged by the discovery of multidomain proteins in which the several domains may have different evolutionary histories. To permit the representation of these complex relationships, the PIRSF system is formally defined as *a network classification system based on evolutionary relationship of full-length proteins* (Wu *et al*., 2004a) (Figure 1).

The primary PIRSF classification unit is the *homeomorphic family* whose members are both *homologous* (evolved from a common ancestor) and *homeomorphic* (sharing full-length sequence similarity and a common domain architecture). Common domain architecture is indicated by the same type, number, and order of core domains, although variation may exist for repeating domains and/or auxiliary domains. Each protein can be assigned to only one homeomorphic family, which may have zero or more parent *superfamilies* and zero or more child *subfamilies*. The parent superfamilies connect related families and orphan proteins on the basis of one or more common domains, which may or may not extend over the entire

lengths of the proteins. The child subfamilies are homeomorphic groups that may represent functional specialization. The flexible number of parent–child levels from superfamily to subfamily reflects natural clusters of proteins with varying degrees of sequence conservation, rather than arbitrary similarity thresholds. While a protein will belong to one and only one homeomorphic family, multidomain proteins may belong to multiple superfamilies (hence, the network structure). A domain superfamily, which consists of all proteins that contain a particular domain, is usually represented by the corresponding Pfam domain (Bateman *et al*., 2004) for convenience.

3. PIRSF case examples

Figure 1 illustrates three PIRSF examples, one with a superfamily (PIRSF800001: Ku70/80 autoantigen), one with subfamilies (PIRSF001969: insulin-like growth factor binding protein, IGFBP), and one with multiple domain parents (PIRSF001499: bifunctional chorismate mutase/prephenate dehydrogenase, T-protein).

Ku is a multifunctional protein found in both eukaryotes and prokaryotes. The eukaryotic Ku protein is an obligate heterodimer of two subunits, Ku70 and Ku80. Ku70 and Ku80, predicted to have evolved by gene duplication from a homodimeric ancestor, share three domains and are placed into one superfamily. They differ, however, at their carboxyl ends, so they form two homeomorphic families (PIRSF003033 and PIRSF016570). The central Ku β-barrel domain (PF02735) is also conserved (without the N- and C-terminal extensions) in several prokaryotes (PIRSF006493). The prokaryotic Ku was predicted (Aravind and Koonin, 2001), and later experimentally confirmed, to form a homodimer involved in repairing double-strand breaks in DNA in a mechanistically similar fashion to eukaryotic Ku-containing proteins.

IGFBPs are a group of vertebrate-secreted proteins that bind to IGF with high affinity and modulate the biological actions of IGFs. These proteins share a common domain architecture, with an N-terminal IGF binding protein domain (PF00219) and a C-terminal thyroglobulin type-1 repeat domain, and are classified into a homeomorphic family (PIRSF001969). These proteins, however, have a highly variable mid-region and diverse functions ranging from the traditional IGF-related role to acting as growth factors independent of the IGFs. Six member types, IGFBP-1 through 6, have been delineated on the basis of gene organization, sequence similarity, and binding affinity to IGFs (Baxter *et al*., 1998). Each of the member types corresponds to a clearly distinguishable clade of the family phylogenetic tree and consists of orthologous sequences from various vertebrate species. Accordingly, six homeomorphic subfamilies (PIRSF500001-500006) are defined. The IGFBP family is related to the MAC25 gene family (PIRSF018239), which shares only the N-terminal IGFBP domain and has a relatively low IGF-binding activity.

Chorismate mutase (CM) (EC 5.4.99.5) and prephenate dehydrogenase (PDH) (EC 1.3.1.12) are two enzymes of the shikimate pathway present in bacteria, archaea, fungi, and plants. The corresponding domains (PF01817, PF02153) occur in proteins with different domain architectures, reflecting extensive domain shuffling. These proteins are classified into several PIRSF homeomorphic families

according to their domain architectures and are assigned family names indicative of their known or predicted functions.

4. PIRSF for functional prediction, database annotation, and protein nomenclature

Sequence analysis and protein classification based on full-length proteins can lead to educated predictions for both generic biochemical and specific biological functions. For example, members of PIRSF005547 are predicted to be feedback inhibition-sensitive PDHs due to the presence of the ACT domain (see Figure 1). The prediction is based on the ACT domain being essential for phenylalanine-mediated feedback inhibition and ligand binding in *Escherichia coli* P-protein (PIRSF001500) (Pohnert *et al*., 1999). Stand-alone versions of the PDH lacking the ACT domain (PIRSF006786) are predicted to be feedback inhibition-insensitive. Another example is PIRSF017318, where the members contain a catalytic CM domain and a unique N-terminal regulatory domain (Figure 1) and are subject to allosteric inhibition by tyrosine and activation by tryptophan. Even though this regulatory domain is not yet defined by any domain database, PIRSF classification points to its existence and provides information about its function.

PIRSF classification can facilitate accurate, consistent, and rich functional annotation of proteins (Wu *et al*., 2003b) and assist with the development of standard protein nomenclature and ontology. A classification-driven rule-based annotation approach (*see* Article 36, **Large-scale, classification-driven, rule-based functional annotation of proteins**, Volume 7) is central to UniProt protein annotation, in particular for transferring functional annotation such as functional sites and protein names from characterized members of a protein family to poorly studied proteins of this family. The multiple levels of sequence diversity improve annotation, allowing for classification of distantly related orphan proteins (usually at the levels of superfamilies and families) and accurate propagation of annotation (usually within families and subfamilies). While annotation can be conveniently propagated for homeomorphic families of closely related proteins, the subfamily level is most appropriate for larger and more diverse families. Standardized nomenclature can be developed on the basis of protein name rules that define standard protein names, synonyms, acronyms or abbreviations, Enzyme Commission (EC) name and number, and even “misnomers” for commonly misannotated proteins. The PIRSF names assigned at different classification levels, from more general to specific names, reflect different degrees of functional granularity and can be used to develop a protein ontology.

5. Accessing PIRSF

The PIRSF database is freely accessible from the PIR website at **http://pir.georgetown.edu/pirsf/**, and supported by the iProClass bioinformatics framework for data integration and associative analysis (Wu *et al*., 2004b). In particular,

PIRSF family classification is directly mapped to other family, function, and structure classification schemes, such as Pfam, InterPro (Mulder *et al*., 2003), and SCOP (Andreeva *et al*., 2004). PIRSF family reports present membership information, other classification schemes, structure and function cross-references, and graphical display of domain and motif architecture. To indicate their curation status, PIRSF families are labeled as "full", "preliminary", or "none", respectively, representing those that are fully curated with description and bibliography, partially curated with membership and domain architecture, or automatically classified and not yet curated. The reports for all curated PIRSF families include additional family annotation and links to multiple sequence alignments and evolutionary trees dynamically generated from seed members. Fully curated PIRSF families are integrated into the InterPro database. More than 20 PIRSF fields are searchable, including other database unique identifiers and annotations such as family name, keywords, and length. For example, one can identify all PIRSFs sharing one or more common Pfam domains, or all PIRSFs in a SCOP fold superfamily. Users can also perform a BLAST search (Altschul *et al*., 1997) of a query sequence to get a list of best-matching families and of all protein sequences above a given threshold.

Short Specialist Review

Equivalog protein families in the TIGRFAMs database

Jeremy D. Selengut and Daniel H. Haft
The Institute for Genomic Research, Rockville, MD, USA

The process of genomic annotation – the assignment of function to nucleotide and protein sequences – involves leveraging a small amount of experimental data and applying it to the maximum number of sequences possible without making significant false statements. Experimental characterizations are often found for particular enzymes in only one or a handful of species, but these activities must be identified over the whole breadth of the sampled tree of life. Owing to the conservative nature of protein evolution, sequences derived from a common ancestor have homology and this homology is generally more pronounced to the extent that the function of the progeny of this ancestor is unchanged. An "equivalog" is defined (Haft *et al*., 2001) as a family of proteins conserved in function since their last common ancestor. This term differs from the more often used term "ortholog", which is not limited to groups with conserved function and is strictly limited to speciation events and excludes horizontal gene transfers (Fitch, 1970). Whereas orthologs are broadly useful objects for determining the process of protein evolution and discriminating the relationships between sequences, equivalogs are most useful in genomic annotation where the conservation of function is a critical factor.

The combination of multiple sequence alignments and phylogenetic analysis (tree-building) is a powerful tool for identifying families of proteins sharing a common ancestry. Multiple sequence alignments of such families can be represented mathematically by Hidden Markov Models (HMMs) such that novel query sequences can be compared and accepted or rejected as members of the family on the basis of a scoring function and a manually determined "trusted" threshold. HMMs that represent equivalog families in the TIGRFAMs database (Haft *et al*., 2003) are generally built either from the bottom up (by identifying a characterized protein, identifying homologs, and pruning away sequences for which the hypothesis of conserved function is not supported) or from the top down (by identifying a family containing proteins of diverse functions and breaking it up into smaller, functionally uniform pieces, see Figure 1).

Since the density of experimentally characterized sequences is sparse, criteria have been developed for supporting or rejecting the hypothesis of conserved function. These criteria are conservative so as to limit the false application of functional information. TIGRFAMs models do, however, contain a "noise cutoff", which is a second, less stringent threshold value. Sequences that score between

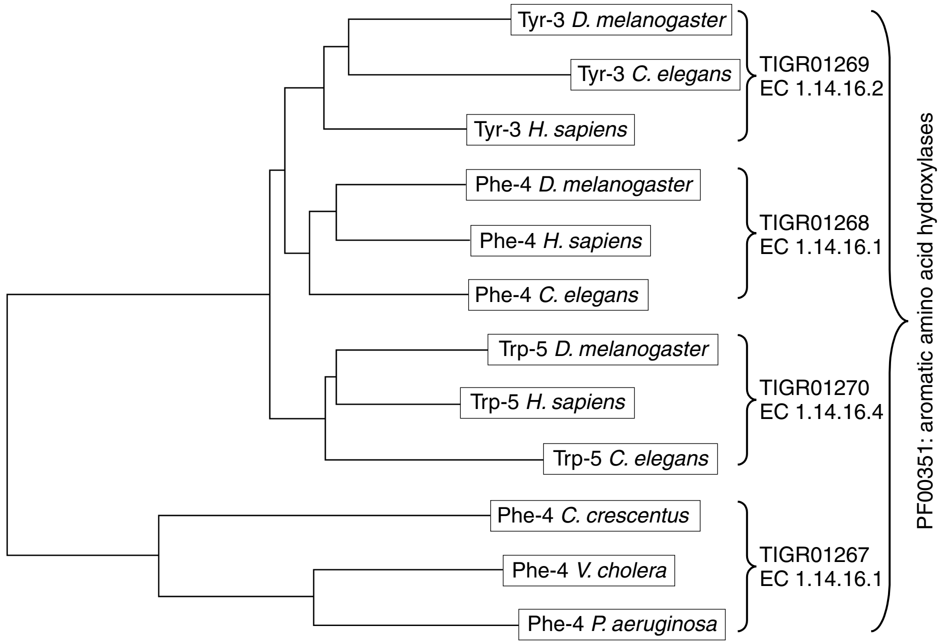

Figure 1 A protein family broken up into equivalogs. The Pfam HMM PF00351 represents a diverse family of aromatic amino acid hydroxylases. A neighbor-joining phylogenetic tree of the family is shown. The position of the root of the tree is supported by alignment versus sequences of greater divergence (not shown). The tree can be broken down into four nonoverlapping pieces representing monomeric eukaryotic tyrosine-3-monoxygenases (Tyr-3), phenylalanine-4-monoxygenases (Phe-4), tryptophan-5-monoxygenases (Trp-5), and tetrameric bacterial phenylalanine-4-monoxygenases (Phe-4). Each piece has been used as the source of sequences in the building of equivalog TIGRFAMs HMMs

the noise and trusted cutoffs will not be annotated automatically, but may be found to have the indicated function based on independent lines of (manually reviewed) evidence. A primary requirement for a TIGRFAMs equivalog model is a properly rooted phylogenetic tree. This is achieved by including in the multiple sequence alignment sequences from a distinct but closely related family. The resulting tree is examined to find the highest branching node encompassing the sequences with experimentally determined functions. The family represented by this highest branching node may be phylogenetically narrow. The family may be broadened (by walking up the nodes of the tree) to include new sequences within certain constraints. No sequence should be included if it has evidence of a different function. With limited exceptions, each species should only be represented once in the family. Supportive evidence such as gene clustering with genes of related function is sought for sequences brought into the family in this way. The tree is also examined to identify sequences with excessively long branch lengths (which may represent functional divergence) to determine if these should be excluded.

Protein families differ from each other in the extent to which function is heterogeneous across the family and in how great the sequence differences are between subsets that perform different functions. Closely related substrates, such as collections of six-carbon sugars, may be acted on by closely related enzymes or

transporters. Proteins from paralogous families in which counts of member proteins differ widely between genomes, characterizations are sparse, and functions often differ between closely related proteins tend to be poor candidates for equivalog model construction. HMMs representing such families are classified as "subfamily", and they identify and provide a warning for cases in which strong sequence similarity easily leads to the error of overly specific annotation.

TIGRFAMs emphasizes models that provide a functionally descriptive name for whole proteins. In contrast, Pfam (*see* Article 86, **Pfam: the protein families database**, Volume 6) (Bateman *et al*., 2004) and SMART (Letunic *et al*., 2004) models tend to mark out larger protein families and make less specific identifications. In some cases, such a model includes proteins with end-to-end homology, but a variety of functions. In other cases, members may share regions of sequence homology, often corresponding to conserved structural domains and referred to as homology domains, while other regions lack homology. Where the emphasis of a Pfam or SMART model may be to extend the sensitivity and selectivity of homology detection beyond that of pairwise BLAST comparisons, TIGRFAMs models often discriminate among rather closely related proteins (Figure 2).

Equivalog HMMs are useful in automatic genome annotation. The information that would be manually attached to each gene by an annotator is instead attached to an equivalog HMM. The HMM is then used to transfer the information automatically to the appropriate genes. This results in not only a significant savings in time but also an improvement in accuracy and data consistency. Groups of equivalog HMMs can be linked together to create computable objects representing proteins that act together in a biological process (such as a metabolic pathway). Such compound objects can be used in metabolic reconstruction and applied to genomic sequence data even prior to annotation. The assignment of process-related annotation information is more labor intensive than assigning molecular functions, requiring an appreciation of the genomic context of the gene in question. TIGR has recently implemented a system to represent such objects (Genome Properties) in part to improve the richness of gene annotation (Haft *et al*., 2004).

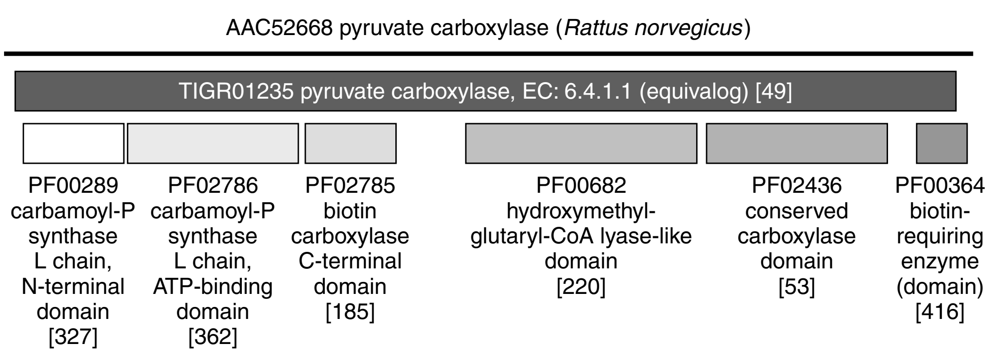

Figure 2 A single TIGRFAMs model, TIGR01235, matches a long protein to which is assigned a particular function, pyruvate decarboxylase. All query sequences that score above the model's trusted cutoff score can be annotated automatically as instances of pyruvate decarboxylase. Meanwhile, six different Pfam HMMs describe nonoverlapping domains, all of which identify additional proteins outside the TIGR01235 family

Short Specialist Review

The CATH domain structure database

Frances Pearl, Christopher Bennett and Christine Orengo
University College London, London, UK

1. Introduction

The CATH protein structural domain database was established in 1993 (Orengo *et al.*, 1997; Pearl *et al.*, 2003) and made available on the World Wide Web in 1994 (**http://www.biochem.ucl.ac.uk/bsm/cath/**). The database currently contains nearly 60 000 structural domains derived from protein structures deposited in the Protein Data Bank (PDB, Berman *et al.*, 2000).

CATH is a hierarchical database in which structures are classified in a manner that reflects a hierarchy of protein folding (see Figure 1). There are four major levels in the hierarchy. At the top, the **C**lass describes the composition of the protein according to the percentage of residues adopting α-helical or β-strand conformations or a mixture of the two ($\alpha-\beta$). The next level, **A**rchitecture, describes the general shape of the structure given by the arrangement of secondary structures in 3D space. The third, **T**opology level, then considers both the arrangement in 3D and the connectivity of the secondary structures. Finally, the **H**omologous Superfamily groups together domain structures that have clearly evolved from a common ancestor. Within each homologous superfamily, close relatives are grouped into families according to levels of sequence similarity (35, 60, 95, 100%) by single-linkage clustering. A list of nonredundant CATH representatives is generated by selecting a single relative from each family clustered at 35% sequence identity (Sreps).

The protocol for classifying new structures in the CATH domain database involves several steps, some of which are fully automated, while others require some manual validation (see Figure 2). In this chapter, we describe the various algorithms used for classification. We also present a short overview of current populations of architectures, fold groups, and superfamilies.

2. Protocol for classifying protein structures in the CATH domain database

As a first step, each protein chain downloaded from the PDB is deconstructed into its constituent domains. Currently, protein chains from both crystal structures with

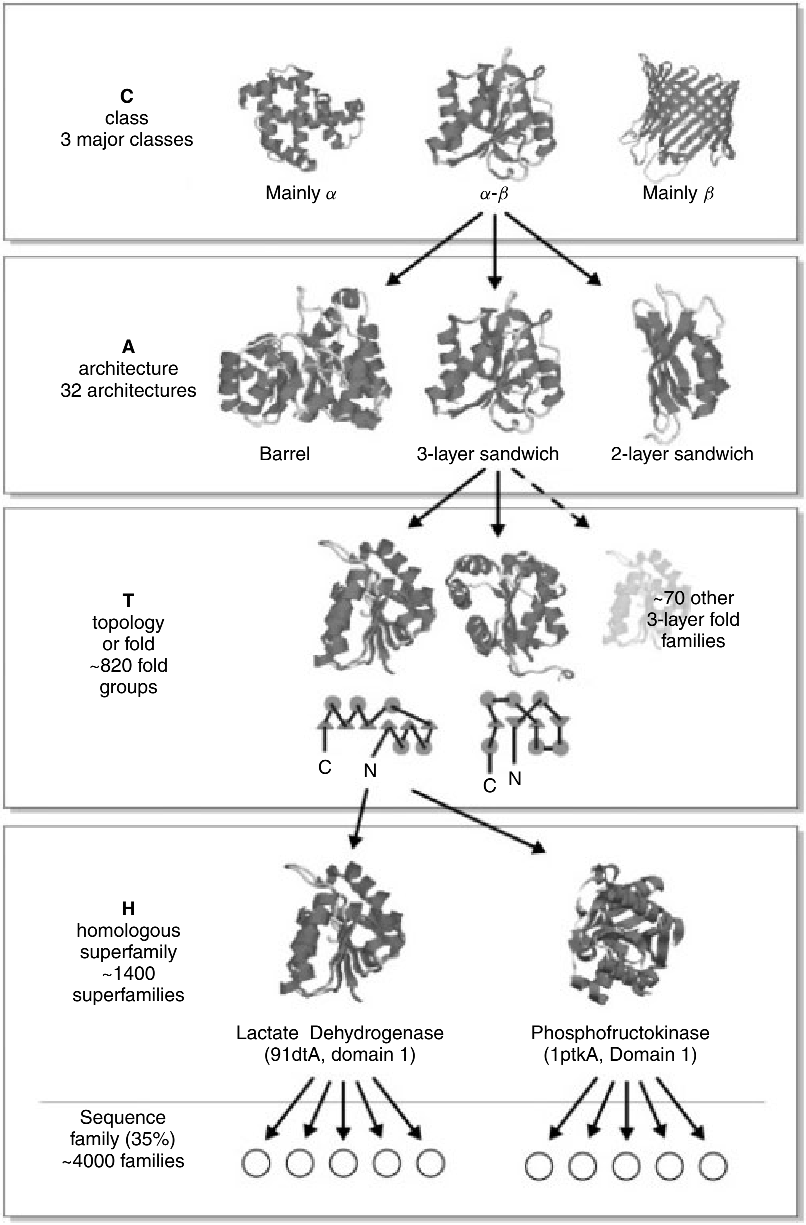

Figure 1 Illustration of the hierarchical nature of the CATH (version 2.5.1) classification scheme. Folds are first assigned to a class contingent on their secondary structure content, and then to architecture that is dependent on their gross geometric shape (e.g., barrel, sandwich, etc.). Each architecture is then divided into fold groups, where each fold has a unique topology. This is dependent on the connectivity between the secondary structures within a fold. Structural domains within a fold group are then clustered into homologous superfamilies, where there is evidence that all members of a superfamily have evolved from a common ancestor. Finally, the homologous superfamilies are grouped into sequence families where all members share sequence similarity > 35% to at least one other member in the family

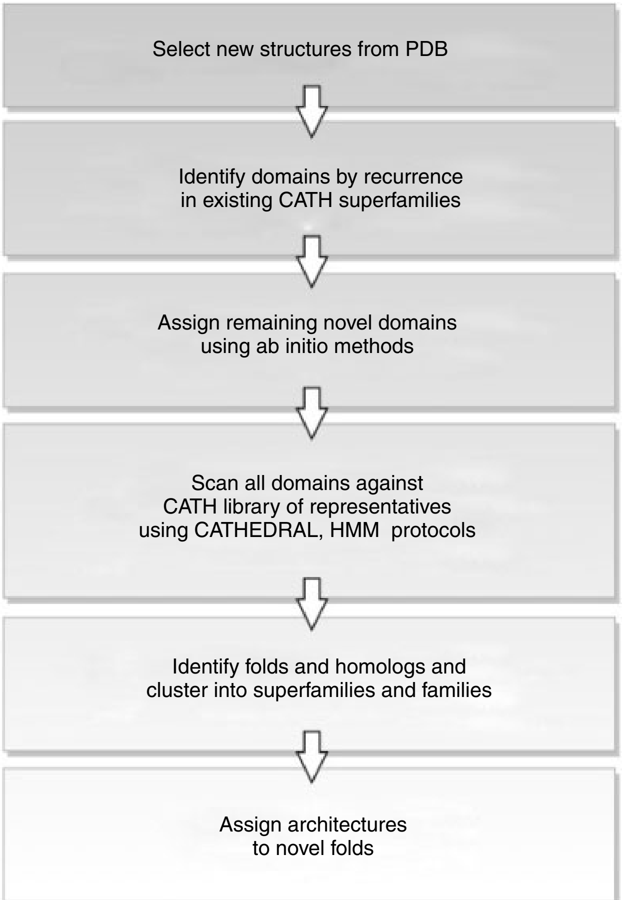

Figure 2 Schematic illustration of the steps required in the classification of protein structural domains

better than 4 Å resolution and NMR structures are considered. Since its inception, CATH has been a domain-based database as domains are thought to be important evolutionary units (*see* Article 82, **Structure comparison and protein structure classifications**, Volume 6). They are much more easily recognized using structural data rather than sequence data; thus, domain structure resources often provide important complementary data to the sequence resources. Structure is also much more highly conserved than sequence and thus the structural data allow more distant evolutionary relationships to be detected than the purely sequence-based resources.

Having determined the domain boundaries of a protein chain, sequence and structure comparison methods are then used to classify the domain into the appropriate fold group and homologous superfamily. Over the last few years, several new methods and protocols have been developed to allow CATH to keep pace with the growing number of structures deposited each year, especially since the onset of the structural genomics initiatives. Currently, 400 new structures are deposited in the

PDB each month. Fortunately, a substantial proportion of these can now be classified using largely automated approaches (see below). The individual steps taken to update CATH, summarized in Figure 2, are discussed in more detail below.

2.1. *Domain boundary assignment*

Two approaches are used for recognizing domain boundaries in multidomain proteins. New structures are first scanned against a library of nonredundant domain folds from CATH in order to recognize any known domain folds CATHEDRAL, see below. This approach exploits the principle of domain recurrence. It has become increasingly clear from genomic analyses that in many protein families domains have been extensively duplicated during evolution (Apic *et al*., 2001) and combined with different domain partners. In a recent CATH release, 75% of protein chains with no significant sequence similarity (sequence identity <35%) to entries in CATH had domains that could be recognized using CATHEDRAL.

Once known folds have been identified and their boundaries refined by manual validation, an ab initio method is used to try to determine whether any remaining regions in the multidomain structure comprise more than one domain.

2.1.1. Methods that exploit domain recurrence

2.1.1.1. Structure-based methods

New PDB structures are scanned against a library of nonredundant structures (Sreps) from the CATH database using a rapid structure comparison method (CATHEDRAL). In parallel, sequences of the new structures are scanned against a library of Hidden Markov Models (HMMs) from representative structural superfamilies.

CATHEDRAL is an acronym that stands for CATH's Existing Domain Recognition Algorithm. The CATHEDRAL suite exploits a fast structure comparison algorithm (GRATH, Harrison *et al*., 2003) that compares secondary structures between proteins using graph theory. CATHEDRAL uses a robust statistical framework based on analyzing the extreme value distribution of scores generated by GRATH'ing a new structure against the CATH fold library, to determine the statistical significance of any fold match.

For each significant match, CATHEDRAL then performs more sensitive residue-based SSAP structure alignment. This is done to obtain an accurate residue-based alignment in order to locate the domain boundary reliably. Matching structures are superposed on the equivalent residues identified by SSAP, using rigid body methods, in order to calculate an root mean squared deviation (RMSD). Several stringent SSAP and RMSD criteria have to be met for a structure match to be confirmed. An iterative process then continues with the remaining regions of the chain scanned against the database until the complete chain has been assigned domains.

In some superfamilies that are highly structurally variable (e.g., the $\alpha\beta$-hydrolases), the SSAP criteria imposed by CATHEDRAL are sometimes too stringent occasionally resulting in a missed similarity. Evidence of a match to

a sensitive sequence profile or HMM can also confirm membership of a particular superfamily. Therefore, all new structures are also scanned against a library of HMMs derived from nonredundant representatives (Sreps) of each superfamily, using the SAM-T99 technology (Karplus and Hu, 2001). Statistically significant matches to any superfamily are identified using the DomainFinder algorithm (Pearl *et al*., 2002) and where necessary, pair-wise SSAPs are run against relatives in that superfamily to obtain the best structural match and locate the boundary more reliably.

2.1.1.2. Ab initio domain assignments

These approaches use structural information alone, such as residue contact data, and compactness measurements. A number of successful algorithms have been developed. Two, DOMAK (Siddiqui and Barton, 1995) and PUU (Holm and Sander, 1994) explore alternative divisions of the protein chain that optimize the number of contacts within domains and minimize contacts between domains. Since internal contacts frequently involve compactly packed hydrophobic residues, other methods (e.g., DETECTIVE, Swindells, 1995) attempt to identify domains by locating hydrophobic clusters, which are then expanded until the packing density falls.

In the CATH classification, the Domain Boundary Suite (DBS; Jones, 1998) integrates these three independent programs (DOMAK, PUU, DETECTIVE) and the resulting boundary assignments are compared automatically. Where all the programs agree, the consensus domain boundaries are accepted automatically. If no consensus is reached, then domain boundaries are derived manually, guided by the predictions.

Using DBS nearly 80% of single domain proteins can be reliably identified. However, as the size and complexity of proteins deposited in the PDB has increased with improvements in technology, the proportion of multidomain proteins that DBS can automatically assign has decreased. Therefore, for those domains with no, partial or conflicting domain assignments, manual intervention is required and the literature is consulted.

2.2. Methods to identify homologs (chains and domains)

As described above, all new structures are scanned against libraries of structural representatives from CATH using CATHEDRAL and their sequences are scanned against HMM libraries to detect significant similarities. Once multidomain proteins have been decomposed into their constituent domains, these are also rescanned against the CATH sequence and structure libraries, to confirm fold and homology assignments. Statistical significance of any match is assessed using the E-value and residue overlap returned by the match. Conservative thresholds are used to minimize the error rate for automatic recognition of homologs and these have been tailored to give the best coverage for any given superfamily.

For remote homologs, the scores often fall below the threshold values and in these cases extensive manual validation is performed to ensure that there is conclusive evidence that the proteins evolved from a common ancestor. This includes detection

of rare sequence and structural motifs and/or conservation of function or of some functional feature; for example, evidence of a conserved chemical mechanism.

2.3. *Recognizing fold similarities and assigning architectures for novel folds*

Any new structure that matches an existing CATH representative but for which there is no evidence of an evolutionary relationship is assigned to the same fold group but as a new superfamily within that fold group. Automatic criteria are used to assign these fold similarities; however, where the empirical and statistical values are borderline, automatic fold assignment is considered unsafe and expert (human) opinion is used. Fold space is better described as a continuum and as recent papers (Harrison *et al*., 2002; Melo *et al*., 2002) have demonstrated, there is often much structural overlap between different folds. Frequently the literature is consulted to resolve these difficult cases.

More interestingly, there are occasionally relatives in structurally variable families that have changed so extensively that they could be considered to have evolved a completely new fold (Grishin, 2001). These relatives are flagged in the CATH relational database (see below) as having an outlying structure and full details on the degree of structural similarity between this structure and other relatives in the superfamily are given in the Dictionary of Homologous Superfamilies (DHS, see below).

New structures that do not match any existing CATH structures are assigned as novel folds and are manually inspected to assign their architecture. There are currently 34 well-described architectures in CATH (5 mainly α, 18 mainly β, and 11 $\alpha-\beta$) and few new architectures have been assigned over the last few years (Pearl and Orengo, 2003).

3. The dictionary of homologous superfamilies (DHS)

The CATH dictionary of homologous superfamilies (DHS, **http://www.biochem.ucl.ac.uk/bsm/dhs**) contains detailed information on each CATH superfamily. For example, sequence and structure similarity scores between relatives in each superfamily and multiple structural alignments for structurally coherent subgroups. These alignments have been annotated with ligand data, where available from the MSD database. Representative plots are presented for each superfamily showing equivalent secondary structures and describing variations in their separations and orientations (2Dsec, EquivSec). Functional descriptions are also provided where they can be extracted from a range of functional databases (EC, Swiss-Prot, GO, COG, KEGG).

4. The CATH relational database and CATH server

All the information on the CATH hierarchy, including domain boundary data, similarity scores within fold groups and superfamilies, is stored in an Oracle 9i

relational database. CATH family data has been integrated with derived structural data (e.g., information on residues in contact with ligands) from the MSD datamart. A reduced version of the data is also available in a Postgres relational database. Web pages are constructed from the database and can be accessed at (**http://www.biochem.ucl.ac.uk/bsm/cath/**). Multiple structure alignments from the DHS are available by ftp from **ftp://ftp.biochem.ucl.ac.uk/pub/cathdata/**. The CATH library of HMMs built from representatives structures (Sreps) is also available from the same ftp site.

New structures can be sent as queries to the CATH server (**http://www.biochem.ucl.ac.uk/cgi-bin/cath/CathServer.pl**), which scans the structures against the CATH fold library using CATHEDRAL to recognize putative domains and then performs pairwise structure comparison using SSAP on representatives from any fold group matched.

5. CATH structural annotations for completed genomes (Gene3D)

Sequences from completed genomes have been scanned against the CATH HMM library in order to identify sequences or partial sequences that can be reliably assigned to CATH structural superfamilies. Conservative thresholds have been applied and conflicting matches resolved using the DomainFinder algorithm (Pearl *et al*., 2001). All the matches have been stored in the Gene3D relational database and can be viewed over the Web (**http://www.biochem.ucl.ac.uk/bsm/cath/Gene3D/**). Currently, between 40 and 70% of genes in completed genomes can be annotated (20–45% by residue), depending on the genome. A CATH intermediate sequence library has also been generated containing CATH sequence relatives in Swiss-Prot/TrEMBL, which currently contains over 600 000 sequences.

6. CATH statistics

CATH version 2.6 contains 22 303 PDB entries comprising 45 903 chains and 60 435 domains. These have been classified into 1569 superfamilies, 907 fold groups and 34 well defined architectures. However, fold groups and superfamilies are not evenly populated. While most of the fold groups (85%) are very small containing a single superfamily, approximately 50 of the largest fold groups in CATH (7% of the total number of fold groups), comprising 3 or more diverse superfamilies, account for nearly 53% of the nonredundant structures in CATH (Sreps). This power law–like behavior is also mirrored in the population of superfamilies. Figure 3 shows that the top 150 most highly populated superfamilies in CATH account for 50% (49%) of the nonredundant structures.

Similar behaviour is observed with the architectures. Although there are currently 34 well-defined architectures in CATH, six regular architectures (α-bundle, $\alpha-\beta$ barrel, 2- and 3-layer$\alpha-\beta$ sandwiches, β-sandwiches, β-barrels) are more highly populated containing 36% of the fold groups and 56% of the nonredundant structures.

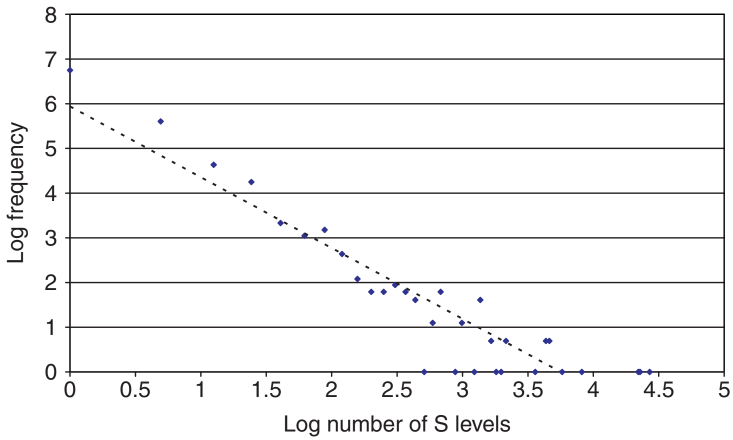

Figure 3 Graph showing the power law–like relationship between the number of sequence families found within the homologous superfamilies

The preponderance of certain architectures and fold groups within the hierarchy may reflect energetically favorable arrangements of secondary structures. For example, the most highly populated architectures all have very regular arrangements of secondary structures, which might be expected to optimize packing of hydrophobic residues in the buried core. Alternatively, it may be the consequence of the extremely divergent evolution of those structural superfamilies that have been extensively duplicated and distributed throughout the genomes (see Apic *et al*., 2001; Lee *et al*., 2003).

In particular, many of the most highly populated fold groups (e.g., TIM barrels, Rossmann folds) are common throughout all kingdoms of life and have clearly been extensively duplicated in the genomes (see Apic *et al*., 2001; Lee *et al*., 2003). Many of them are performing generic functions such as provision of redox equivalents or energy for a catalytic reaction. Paralogs frequently adopt new functions (Todd *et al*., 2001) thus removing some of the constraints on structural change and allowing the protein to diverge beyond the point at which an evolutionary relationship can be easily detected using current methods.

Interestingly, a significant proportion of newly determined structures can be assigned to existing superfamilies and fold groups within CATH, suggesting that we may now have representatives of most of the major protein superfamilies in nature. Clearly, the membrane-bound structures are still an important exception and still underrepresented in the structural databases. A recent analysis by Todd *et al*. (2004) has shown that nearly 80% of newly determined structures, solved within the last year, could be classified in CATH using sophisticated sequence profiles and HMMs. A further 15% could be assigned to structural families and fold groups using structure-based comparison (CATHEDRAL, SSAP). The remaining 5% of structures were novel folds the majority of which could be assigned to existing architectures within the classification.

Short Specialist Review

COGs: an evolutionary classification of genes and proteins from sequenced genomes

Eugene V. Koonin
National Institutes of Health, Bethesda, MD, USA

1. Introduction

The rapid accumulation of genome sequences is both a tremendous opportunity and a major challenge to biologists attempting to extract the maximum functional and evolutionary information from the new genomes (Koonin and Galperin, 2002). With hundreds of genomes being sequenced, each consisting of thousands of genes (Bernal *et al*., 2001), an informational overflow is inevitable unless an approach is developed to classify these genes in such a manner that the number of individual entities to be examined is drastically reduced. Since all genomes are products of evolution, a natural classification of genes should be based on their evolutionary relationships. More specifically, two fundamental concepts of evolutionary biology are central to such classifications: orthology and paralogy, which describe the two distinct types of homologous relationships between genes. Orthologs are homologous genes derived by vertical descent from a single ancestral gene in the last common ancestor of the compared species. Paralogs, in contrast, are homologous genes, which, at some stage of evolution of the respective gene family, have evolved by duplication of an ancestral gene (Fitch, 1970; Fitch, 2000). Orthology and paralogy are intimately linked because, if a duplication(s) occurred after the speciation event that separated the compared species, orthology becomes a relationship between sets of paralogs (co-orthologs), rather than individual genes (Sonnhammer and Koonin, 2002). Disentangling orthologous and paralogous relationships among genes is critical for functional and evolutionary genomics. Orthologs typically occupy the same functional niche in different species, whereas paralogs evolve toward functional diversification. Therefore, robustness of genome annotation depends on accurate identification of orthologs. Similarly, knowing which homologous genes are orthologs and which are paralogs is required for constructing evolutionary scenarios that involve, in addition to vertical inheritance, lineage-specific gene loss and horizontal gene transfer.

2. Clusters of Orthologous Groups of proteins (COGs)

These principles outlined above became the foundation of an evolutionary classification of proteins from sequenced genomes, which was developed at the National Center for Biotechnology Information in 1997 (Tatusov *et al*., 1997). This classification system was named Clusters of Orthologous Groups of proteins, or COGs, to emphasize the fact that a classification unit included not only orthologous proteins but also paralogs resulting from duplications that apparently occurred in one or more species subsequent to their divergence (in-paralogs). The procedure for constructing COGs is based on clustering the matrix of the all-against-all comparison of the proteins encoded in the analyzed genomes; the comparison is performed using the BLAST program (Altschul *et al*., 1997) although, in principle, other methods for sequence comparison can be employed. The clustering procedure was designed to explicitly exploit the notion of orthology: orthologous protein sequences from two species normally are more similar to each other than any of them is to any other sequence from the same genomes. Thus, to form COGs, clusters of mutually consistent, genome-specific best hits (most similar sequences) are identified, after which in-paralogs are added by assigning to COGs the sequences that remained unassigned at the first step. This procedure allowed incorporating into COGs both slowly evolving and fast-evolving proteins, without imposing arbitrary statistical cutoffs on sequence similarity. Additionally, a semiautomatic procedure was developed for handling mutlidomain proteins, in which two (or more) distinct portions of the protein (domain) have different evolutionary histories and belong to different COGs.

The original collection of COGs included six prokaryotic genomes and one genome of a unicellular eukaryote, the yeast *Saccharomyces cerevisiae* (Tatusov *et al*., 1997). Simultaneously with the procedure for COG construction, a method was devised for updating the collection, that is, assigning proteins from newly sequenced genomes to COGs. This method, implemented in the COGNITOR program, is based on the same principle as the original COG-making procedure, that is, genome-specific best hits. Proteins from a new genome that consistently show best hits to proteins from the same COG are included in this COG. The construction of the COGs was followed by manual annotation of the known or predicted functions of each COG by expert biologists. The COG system was updated several times since its inception (Tatusov *et al*., 2000; Tatusov *et al*., 2001; Tatusov *et al*., 2003) and currently includes 63 prokaryotic and 7 eukaryotic genomes (as of January 1, 2004). The procedure for COG construction required that each COG included proteins from at least three sufficiently distant species. This conservative approach notwithstanding, ~60 to ~85% of the proteins encoded in prokaryotic genomes were included in the COGs (Tatusov *et al*., 2003). The coverage of eukaryotic genomes is somewhat lower but exceeds 50% for each included species (Koonin *et al*., 2004). The data on the COG membership of proteins from selected prokaryotes and eukaryotes are shown in Table 1. That the majority of the proteins from each of the analyzed genomes could be included in clusters of orthologs is an important observation in itself because it quantitatively demonstrates the prevalence of evolutionary conservation in genome evolution and emphasizes the utility of comparative genomics in functional and evolutionary studies.

Table 1 Coverage of bacterial, archaeal, and eukaryotic genomes in COGs

Species	Number of annotated proteins	Number (and percentage) of proteins in COGs	Number of COGs that include the given species
Bacteria			
Escherichia coli K12	4279	3623 (85%)	2131
Helicobacter pylori J99	1491	1106 (74%)	921
Bacillus subtilis	4112	3125 (76%)	1771
Mycoplasma genitalium	484	385 (80%)	362
Mycobacterium tuberculosis H37Rv	3927	2843 (72%)	1450
Mycobacterium tuberculosis CDC1551	4187	2756 (66%)	1434
Mycobacterium leprae	1605	1180 (74%)	927
Treponema pallidum	1036	737 (71%)	639
Archaea			
Archaeoglobus fulgidus	2420	1953 (81%)	1244
Methanocaldococcus jannaschii	1758	1448 (82%)	1117
Methanosarcina acetivorans	4540	3142 (69%)	1462
Sulfolobus solfataricus	2977	2207 (74%)	1084
Eukaryota			
Saccharomyces cerevisiae	6338	3012 (48%)	1299
Encephalitozoon cuniculi	1996	1105 (55%)	696

The COG system, accompanied by the COGNITOR program, has become a widely used tool for computational genomics. The most important applications of the COGs are functional annotation of newly sequenced genomes and genome-wide evolutionary analyses. It has been shown that a considerable accuracy of assignment of proteins to COGs (<5% false-positives) can be achieved even through automatic application of COGNITOR (Natale *et al*., 2000). These results can be further improved through relatively straightforward manual intervention. With regard to evolutionary analysis, the COGs immediately provide valuable information on phyletic patterns of genes, that is, the patterns of presence–absence of genes in species and taxa (this can be done on-line using the phyletic pattern search tool). Strikingly, only ∼1% of the COGs are ubiquitous, that is, represented in all analyzed species; the rest are missing in some genomes (Figure 1). In many cases, lineage-specific gene loss, horizontal gene transfer, or a combination thereof best explains the observed phyletic patterns. Even a superficial examination of the phyletic patterns clearly demonstrates the major importance of these processes in evolution, at least in prokaryotes. The phyletic patterns can be used for more sophisticated evolutionary analyses with maximum parsimony and maximum likelihood methods (Mirkin *et al*., 2003; Snel *et al*., 2002). The COGs also present excellent starting material for genome-wide construction of phylogenetic trees and other evolutionary reconstructions (Wolf *et al*., 2002).

The COGs face the major challenge of keeping up with the ever-increasing rate of genome sequencing. If this challenge is met, the utility of the system for

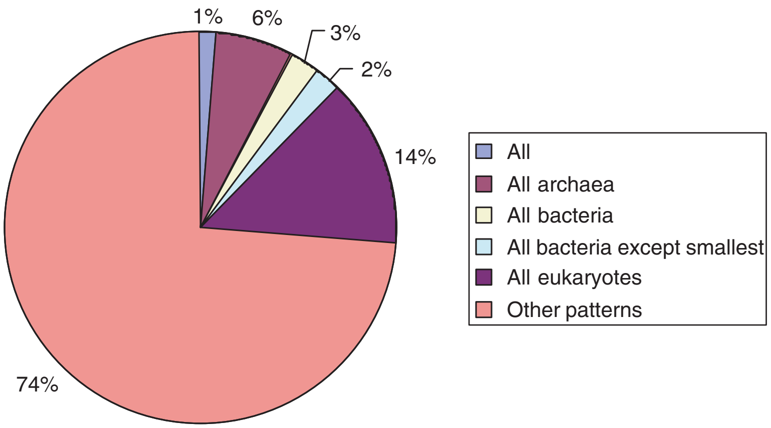

Figure 1 Phyletic patterns of COGs. *All*, represented in all unicellular organisms included in the COG system; *All archaea, All bacteria, All eukaryotes*, represented in each species from the respective domain of life (and possibly in some species from other domains); *All bacteria except the smallest*, represented in all bacteria except, possibly, parasites with small genomes (mycoplasma, chlamydia, rickettsia, and spirochetes)

both functional annotation of genomes and large-scale evolutionary analyses should increase progressively with the inclusion of new species from diverse taxa.

The COGs are accessible at **http://www.ncbi.nlm.nih.gov/COG/** and **ftp://ftp.ncbi.nih.gov/pub/COG/**.

Short Specialist Review

PANTHER: Protein families and subfamilies modeled on the divergence of function

Paul D. Thomas
Director, Evolutionary Systems Biology Group, SRI International, Menlo Park, CA, US

1. Overview

Related protein sequences have diverged both in sequence and in function over evolutionary time. The aim of Protein Analysis Through Evolutionary Relationships (PANTHER) is to group protein sequences into subfamilies of shared function. This aim is accomplished by first grouping sequences into families, and then, if there are proteins with different functions within the family, dividing the family into subfamilies using both computational tools and human expertise. PANTHER therefore allows detailed analysis of the relationship between sequence evolution and function evolution across a large number of protein families. The main applications of PANTHER have been in the following areas: annotation of protein function for genome projects (Venter *et al*., 2001; Mi *et al*., 2003); high-level overview and browsing of whole genomes by function and sequence relationships (Kerlavage *et al*., 2002; Mi *et al*., 2005); analysis of genome-wide experiments, such as mRNA and protein expression data, to find evidence of coordinated activity of particular biological processes and pathways (Clark *et al*., 2003; Freeman *et al*., 2005); and analysis of genetic mutations or variations (single nucleotide polymorphisms, or SNPs) that cause an amino acid substitution in a particular protein (Thomas and Kejariwal, 2004; Brunham *et al*., 2005). PANTHER is freely available at **http://www.pantherdb.org**.

Introduction to protein families, orthologs, paralogs, and functional divergence. The function of a protein molecule is determined by its amino acid sequence. Most known proteins, either from the same organism or from different organisms, can be grouped into "families" of sequences that are recognizably similar to each other, despite millions, and in some cases billions, of years since their divergence from a common ancestral sequence. This sequence similarity persists because some parts of the sequence cannot be changed without lowering the fitness of the corresponding gene, usually by impairing the function of the protein. These essential parts of the protein are therefore "conserved" during evolution.

Protein families have been built up over time by two processes: *copying* of an ancestral sequence, and then *divergence* from that sequence. In general,

there are two ways to generate a copy of a sequence. The first is speciation, in which two genes in two different species descend from the same single gene in the ancestral species (resulting in orthologous genes). The second is gene duplication, in which a gene is copied within a gamete during meiosis, and this duplication then spreads throughout the population, usually due to selective advantage (resulting in paralogous genes). In many cases, orthologous proteins retain the ancestral function, so most of the sequence changes that accumulate over evolutionary time have little effect on the protein's function (i.e. they are selectively neutral). For duplicated genes, on the other hand, because there are now two copies of the same gene, one copy is now freed of prior functional constraints and can therefore take on new or modified functions through mutations in its sequence. As a paralog adapts to its new function, it will tend to change in sequence relatively rapidly (a larger proportion of mutations will be beneficial). Given enough time it will thus form a distinct subfamily that is clearly separated from the ancestral subfamily. The sequence changes that were essential for the new or modified function will be conserved within the subfamily but differ from other subfamilies. The presence of distinct subfamilies of protein sequences, then, allows inference of a *divergence in function* between these subfamilies.

These relationships can be represented as a tree such as the one in Figure 1, where branch lengths represent sequence divergence from the inferred common ancestor. Figure 1 shows a portion of a larger tree of G protein coupled receptors (GPCRs) with two related but distinct functional subfamilies, Dopamine D1 Receptor (D1R) and Serotonin 4 Receptor (5-HT4). While both D1R and 5-HT4 proteins signal through the large G protein signaling pathway, they do so in response to very different extracellular ligands (dopamine vs. serotonin), resulting in a very different physiological response. D1R is found in both vertebrates and invertebrates (and therefore predates the protostome-deuterostome divergence), while 5-HT4 is found only in vertebrates. One possible evolutionary history is that the ancestral D1R gene was duplicated in the vertebrate lineage. One copy then diverged in function, and therefore in sequence, to recognize serotonin and become the 5-HT4 gene. The

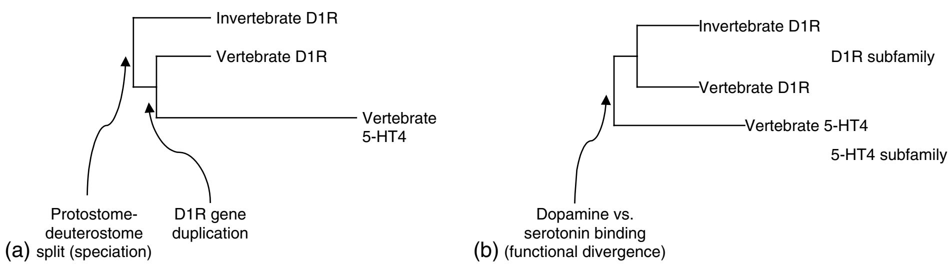

Figure 1 Phylogenetic tree (a) compared to sequence similarity tree (b) for dopamine D1 receptors (D1R) and serotonin type 4 receptors (5-HT4). The tree was built from protein sequences from a number of different invertebrate and vertebrate organisms (see **http://www.pantherdb.org/panther/family.do?clsAccession=PTHR19266** for complete data set) and is summarized here omitting the specific sequences in each group. While the phylogenetic tree represents evolutionary events, the sequence similarity tree represents the selective constraints on different subfamilies, which serves as a basis for correlating sequence with function

vertebrate D1R gene retained dopamine binding and was therefore constrained to conserve the amino acids responsible for this specificity. Assuming this history, a "true" phylogenetic tree would show two copying events: first a speciation (the protostome-deuterostome split), then a gene duplication in the vertebrate lineage followed by rapid sequence evolution along the 5-HT4 branch. The resulting tree (Figure 1A) does not group the sequences by function. However, if we build the tree using sequence similarities instead (Figure 1B), vertebrate D1R appears in the same subtree as invertebrate D1R, while 5-HT4 proteins from different vertebrates form a separate subfamily where all members share more sequence similarity between themselves than they do with the D1R subfamily. For representing sequence-function relationships, a sequence similarity tree is therefore often more useful than a true "phylogenetic" tree.

PANTHER aims to represent these subfamily relationships for all protein families, and currently has high coverage of known metazoan and yeast proteins. For each of over 5000 protein families, a sequence similarity tree is generated and divided by expert biologists into functional subfamilies, modeling the relationships between sequence and function on a large scale.

2. PANTHER: From protein sequences, to subfamilies annotated by function, process and pathway

The entire process for constructing PANTHER families and subfamilies has been described in detail (Thomas *et al*., 2003; Mi *et al*., 2005), and is summarized briefly here. The first step is to cluster proteins into *families* according to their sequence relationships. Our definition of a protein family is designed to facilitate the goal of finding functional subfamilies: a family should be as large as possible, but the sequences should be similar enough to build an accurate multiple sequence alignment. A multiple sequence alignment specifies "equivalent" positions in different proteins (i.e. deriving from a common amino acid in the ancestral sequence for all aligned sequences), so accurate alignment is critical for modeling of molecular evolutionary events.

The second step is to divide protein families into *subfamilies* based on divergence in sequence and function. To accomplish this, we first build sequence similarity trees for each family, and then annotate each protein in the tree with information about its function, species, and protein domains. A biologist curator then reviews the tree structure and protein annotations, and "cuts" the tree into subtrees (subfamilies) that result from inferred functional divergence events. Subfamilies often correspond to groups of orthologous sequences, but we allow the curator to define subfamilies on a case-by-case basis since their inferences will depend on many different factors, such as the details of the biology, the evolutionary trajectory, and the current state of knowledge about the given proteins.

The expert curator then associates each subfamily with controlled vocabulary (ontology) terms that describe the molecular function(s) of the proteins in the subfamily and the biological processes they are known or inferred to participate in. This is important because it provides a way for biologists to perform genome-wide analyses, by looking at a relatively small number of biologically relevant

categories rather than, for example, each of the more than 20 000 distinct human protein-coding genes. The PANTHER ontology terms are a selected subset of the terms available in the Gene Ontology (Gene Ontology Consortium, 2000). In addition to ontology terms, PANTHER also associates protein sequences with a growing number of biological pathways, including both signaling and metabolic pathways. For these proteins, expert curators capture in detail catalysis reactions and protein–protein interactions, using the process notation of Kitano (2003).

Finally, the sequences in each group (both families and subfamilies) are used to build statistical models that represent the sequence diversity in each group. The statistical modeling follows the Hidden Markov Model (HMM) formalism developed by Haussler (Krogh *et al*., 1994). In short, an HMM provides, for each aligned position in a group of sequences, the probabilities of observing each of the 20 amino acids at that position, as well as the probabilities that the position will either be deleted or harbor insertions relative to other sequences in the family. The resulting "library" of family and subfamily HMMs can classify new protein sequences according to the best family and subfamily matches, and can also estimate the importance of a given position for function, based on a quantitative measure of evolutionary conservation (Thomas and Kejariwal, 2004).

Short Specialist Review

Functional prediction through phylogenetic inference and structural classification of proteins

Kimmen Sjölander and Chelsea Specht
University of California, Berkeley, CA, US

1. Functional classification of genes is a pressing need in the genome era

With tens of thousands of new genes being identified monthly, experimental determination of gene function for all new genes is not possible. Thus, computational prediction of gene function is an essential tool for modern biologists. The primary method of gene functional annotation employs transfer of annotation from the top hit in a database search. Because homology-based methods of function prediction have been shown to be prone to systematic errors (Galperin and Koonin, 1998; Koski and Golding, 2001), methods in recent years have focused on inclusion of information from evolutionary studies and structural analysis. In this paper, we present a perspective on the use of phylogenetic and structural analyses for improving the inference of protein function.

2. Structural and functional divergence in protein superfamilies

Evolutionary processes, particularly gene duplication and domain shuffling, produce protein superfamilies that often span a bewildering variety of functions and exhibit extreme structural and sequence divergence. Evolutionary pressures to conserve function (e.g., binding pocket positions that determine enzyme substrate specificity or receptor–ligand interaction) or structure (e.g., disulfide bridges in secreted proteins) can be relieved as gene duplication events permit the family as a whole to innovate novel functions and structures; one copy maintains the original function (with consistent constraints at key sites) while the other is enabled to achieve novel function (termed *neofunctionalization*) or to specialize for different tissue types or temporal needs (termed *subfunctionalization*). If not considered appropriately, the

resulting sequence divergence can cause complications in determining homology and interpreting phylogenetic signal. If the underlying assumptions of phylogenetic analyses are taken into consideration, however, they can provide powerful tools for inferring protein function.

3. Phylogenetics and protein superfamilies

The first assumption of a phylogenetic reconstruction is that the data being analyzed are *homologous*, that is, related by evolution. One of the major challenges in phylogenetic reconstruction of protein superfamilies is that not all positions are homologous across all family members; some regions of proteins may have been inserted or deleted over time (e.g., insertions at surface loops). These positions may not be easily distinguishable from distantly related regions that are homologous, albeit with low sequence similarity. It is critical to differentiate homologous and nonhomologous regions at the outset, perhaps by alignment masking protocols, else the phylogenetic analysis may be adversely affected. This remains a challenge in practice.

Other issues in phylogenetic analysis of protein superfamilies arise due to lineage-specific or site-specific rate variation. While most phylogenetic tree inference methods may allow site-specific rate variation, few attempt to model different types of conservation within different lineages at individual positions. Site-specific mutation rates can vary across sites within a lineage, and can be entirely different from rates observed in other lineages. Both lineage and site specificity are considered independently (Muse and Gaut, 1994; Yang, 1998; Yang and Nielsen, 1998; Nielsen and Yang 1998; Yang *et al*., 2000) and together (Yang and Nielsen, 2002) in a variety of models. These models may be appropriate when some positions are conserved within a particular lineage (e.g., substrate specificity determining residues) but vary across lineages. In other cases, residues observed to interact in the buried core of proteins often exhibit correlated or compensatory mutations. If appropriately incorporated in a phylogenetic analysis, these types of conservation can be used to help determine phylogenetic relatedness.

For example, G-protein coupled receptors (GPCRs) span dozens of different subtypes developed by multiple gene duplication events. Small modifications at key positions determine the ligands recognized by these receptors, for example, serotonin, dopamine, histamine, acetylcholine, chemical odorant signals, chemokines, and opiates. Residues at these positions determine the ligand-specificity of each protein, and thereby its molecular function. Phylogenetic methods that can identify these positions *a priori* could upweight these positions in tree topology estimation. The SATCHMO (Edgar and Sjolander, 2003) algorithm is an example of this type of phylogenetic inference approach.

Phylogenies, or evolutionary trees, are the fundamental structures that enable us to visualize evolution in a hierarchical and comparative framework. Molecular phylogenetic methods have been primarily developed for and validated with respect to inferring the evolutionary history of organisms and gene families based on DNA sequence data. When protein evolution has been examined, it has been in the context of a single group of orthologous genes. In recent years, the challenges of inferring

molecular function for hundreds of thousands of unknown genes have driven the application of phylogenetic approaches to elucidating the evolutionary history of protein superfamilies. Within a family of proteins, sequences with known functions can be grouped with proteins of unknown function in a phylogenetic context, and proteins that group together phylogenetically may be predicted to share a common function. This approach is called *phylogenomic inference of protein function* (Brown and Sjölander, 2006).

4. The objective of protein superfamily phylogenetic analysis

Unlike the primary objective of organismal phylogenetic analysis – elucidating the evolutionary history of an organism or lineage of organisms – the primary objective for most phylogenetic analyses of protein families is protein function prediction. Phylogenomic inference of protein function – the analysis of a protein sequence in the context of a larger protein family with potentially numerous functional subtypes – is a prime example of this type of analysis.

Phylogenomic inference of protein function has several distinct challenges. First, accurate phylogenomic inference depends on homologs with the same domain structure; this is not normally known for sequences found in database search. Most database searches return sequences that may have only local homologs (i.e., have a different domain architecture from the seed). (Brown and Sjölander, 2006). Second, many protein families span large evolutionary distances, resulting in significant structural divergence among homologs and reduced alignment accuracy (Baker and Sali, 2001). While closely related sequences (e.g., with pairwise identities $>50\%$) are normally clustered into subtrees consistently by most phylogenetic tree methods, the branching order between these conserved clades can be very different from one phylogenetic tree method to the next. This is particularly problematic if function inference is based on the branching order observed in a single phylogenetic tree, and other phylogenetic trees for the same dataset are not examined.

In contrast to the issues involved in reconstructing phylogenies for groups of single orthologous genes, phylogenetic reconstruction of protein superfamilies has a greater degree of uncertainty and variability, due to choices made in gathering homologs, constructing a multiple sequence alignment (MSA), alignment masking, choice of phylogenetic method, and phylogenetic tree interpretation. We discuss each of these points in turn.

4.1. Selecting homologs

Accurate phylogenetic reconstruction requires adequate sampling of all the major evolutionary subgroups. Engineered sequences should be excluded, and sequences should be filtered to remove those not sharing the same overall domain structure. The Berkeley Phylogenomics Group FlowerPower server enables selection of

sequences that can be predicted to share the same domain structure as an input seed sequence.

4.2. *Constructing a multiple sequence alignment*

Phylogenetic analysis and alignment construction are integrally related: most phylogenetic analyses are based on input MSAs, which encode the primary source of evolutionary signal upon which the phylogenetic tree construction method operates. The MSA represents the primary statement of homology, such that each column of DNA sequence or amino acid data is considered to be derived from a common ancestor as a single evolutionary event. All methods for alignment therefore inherently make inferences about evolution, and errors in the input alignment can be positively misleading to the phylogenetic analysis.

Progressive alignment methods, such as ClustalW (Thompson *et al*., 1994), construct a "guide tree" developed by distance-based methods to determine the order in which sequences are aligned; alignments are fixed within subgroups as sequences are progressively aligned. Progressive methods are among the most popular, but are primarily appropriate for closely related sequences with few required *indel* characters. Assessment of sequence alignment accuracy relative to structural superposition of 3D solved protein structures shows alignment accuracy drops sharply for pairs of sequences with <30% identity. Datasets including such highly divergent sequences will require more advanced and computationally intensive alignment methods. More recently, iterative methods have been developed that allow sequences to realign and thereby improve the overall accuracy (e.g., MUSCLE (Edgar, 2004), ProbCons (Do *et al*., 2005), and MAFFT (Katoh *et al*., 2005).

4.3. *Masking protocols*

The general consensus among computational biologists is that masking protocols ought to be employed, so that ambiguously aligned columns, or regions of questionable homology, are excluded from the phylogenetic analysis. The relative pros and cons of different masking protocols are not well understood.

4.4. *Selection of phylogenetic tree method*

There are two main classes of molecular phylogenetic analysis: character-based (e.g., maximum parsimony (MP), maximum likelihood (ML) and Bayesian approaches) and distance methods (e.g., neighbor-joining). Distance methods work by estimating a matrix of pairwise distances between input sequence data. These distances are then used to construct a tree topology that is most consistent with all observed pairwise distances. Character-based approaches, by contrast, retain the character state information in estimating a phylogenetic tree that is based on some optimality criterion (i.e., MP searches for the shortest tree consistent with the data, and ML methods attempt to find the most likely tree given the data and some model

of evolution). Distance methods have the primary advantage of being computationally efficient, and are therefore often used by biologists estimating phylogenies for large datasets. However, they are not believed to be as accurate as character-based approaches in estimating tree topology and branch lengths (Yang, 1994), both of which are essential to accurate functional inference by phylogenetic analysis.

Despite inherent controversy, recent years have seen Bayesian methods making a large contribution to phylogenetic inference (Yang and Rannala, 1997; Li *et al*., 2000; Huelsenbeck *et al*., 2001). Controversy surrounds the selection of a prior and its overall contribution to the resulting tree topology; however, the use of Markov-chain Monte Carlo algorithms to rapidly explore tree space makes model-based phylogenetic reconstruction and determination of statistical topological support attainable, even for large and variable datasets. The ability of Bayesian methods to elucidate the evolutionary history of protein superfamilies has not been fully explored, but we believe this class of phylogenetic method has great potential in this area due to the probabilistic nature of the analyses combined with computational speed.

4.5. Assessing phylogenetic method accuracy

The accuracy of phylogenetic methods has traditionally been assessed by simulation studies. In a simulation study, the parameters of a phylogenetic model are predetermined (forming the "true" tree topology), and data is generated from those parameters. These data are then used as input to a phyologenetic tree estimation, and the estimated tree is compared to the "true" tree. The sensitivity of a phylogenetic method to violations of assumptions can then be assessed. Simulation studies have demonstrated the sensitivity of both distance and character-based methods to variations in evolutionary rates across taxa, to site-specific mutation rates and to shifts in evolutionary rates over time (see Swofford *et al*., 1996; Felsenstein, 2004).

4.6. How informative are these simulation studies to phylogenetic reconstruction of protein superfamilies, especially in cases of significant structural divergence due to gene duplication?

Structural studies have shown that as sequence similarity decreases, the degree of structural superposability (of solved 3D structures) also drops. Extremes of structural and sequence divergence is common in protein superfamilies. However, to our knowledge no simulation studies have assessed the impact of the types of evolutionary innovations and dramatic changes observed in multigene families on the accuracy of phylogenetic reconstruction. In fact, most simulation studies and comparisons of methods for phylogeny reconstruction are performed based on two assumptions; that the data being analyzed come from a single orthologous gene family and that the alignment is correct. The first assumption is automatically nullified for protein superfamilies, and studies of alignment accuracy under significant sequence divergence show that the second assumption must also be

assumed to be false. The degree to which errors in the input MSA affect the phylogenetic tree topology accuracy for large protein superfamilies is not known.

4.7. *Using multiple approaches*

Because different tree methods can produce dramatically different tree topologies for the same input MSA, careful attention must be paid to the assumptions made during phylogenetic inference. We recommend applying more than one discrete tree-building method to the data in order to better understand the data and their response to phylogenetic analysis. The wide range of available models provides tools for exploring data while developing a robust phylogenetic hypothesis. If well-supported nodes are in conflict when different tree-building algorithms are used, manipulations of the data (removing characters) and the taxa/proteins (removing taxa) may be necessary to test for underlying conflict in the data set. Davis *et al.* (1998) and Gatesy *et al.* (1999) give reviews of various means of testing for phylogenetic incongruence, data decisiveness, and hidden support in phylogenetic data in a parsimony framework, while Kishino and Hasegawa (1989) review support and conflict in a likelihood framework.

5. Assessing the accuracy of phylogenetic methods and phylogenetic trees

Both parametric and nonparametric means are used for assessing the amount of uncertainty in a phylogenetic tree. The likelihood ratio test (Goldman, 1993) provides a means of the testing assertions about the parameters of the chosen model of evolution, using the ML estimate and comparing it with alternative topologies that cannot be rejected based on their likelihood score. Interior branch tests (Nei *et al.*, 1985; Li, 1989; Tajima, 1992; Rzhetsky and Nei 1992) use the variance on the estimate of the length of a branch in the interior of a tree to determine the reliability of the branch. Both of these are limited by the fact that they are parametric in nature and may underestimate the uncertainty for a given topology. Resampling techniques such as the bootstrap (resampling with replacement: Felsenstein, 1985) and jackknife (resampling without replacement: Mueller and Ayala, 1982; Farris *et al.*, 1996), decay indices (Bremer, 1992; Baker *et al.*, 1998) and data decisiveness tests (Davis *et al.*, 1998) use empirical information about character variation to infer confidence in tree topology. In Bayesian analyses, support for relationships is determined by posterior probabilities of the identified nodes. These values tend to be inflated relative to bootstrap/jackknife values and may not be directly correlated with respect to indication of nodal support (Douady *et al.*, 2003).

6. Computational efficiency

The complexity of protein superfamily evolution begs for more complex models of molecular evolution. Unfortunately, most protein families have large numbers

of taxa (in the hundreds or thousands) as well as significant sequence divergence (many pairs with $<15\%$ identity) while the sequence length is relatively short (at most a few hundred residues in length). This leaves very little actual information to estimate complex phylogenetic models. In addition, model complexity increases the risk of overparameterization, leading to decreased support for any phylogenetic hypothesis.

Many of the phylogenetic questions typically addressed by functional and structural biologists require supercomputers or clusters to run the algorithms necessary to adequately align the data and construct a reliable phylogenetic tree in a reasonable amount of time. Bayesian methods promise to reduce the time necessary for a model-based approach using Markov-chain Monte Carlo simulations of character space.

While these evolutionary reconstructions of protein superfamilies are undoubtly computationally demanding, we believe that the need for function prediction accuracy warrants the time and resources spent on phylogenetic reconstruction. The field as a whole will benefit from simulation studies specifically designed to assess the expected accuracy of existing methods for protein superfamily reconstruction.

7. The role of structure prediction and analysis in protein function prediction

Structural analysis efforts and structural classification databases often have a similar intent: enabling biologists to infer molecular function on the basis of structural similarities. For example, SCOP and CATH enable biologists to make inferences of protein function based on structural similarity, and the DALI and VAST servers provide on-the-fly identification of structural neighbors for newly solved structures. A variety of webservers enable prediction of structural domains through the use of profile or hidden Markov model approaches (e.g., 3d-pssm, the NCBI Conserved Domain Database, and Superfamily). Several methods that integrate structural and phylogenetic analyses have been successfully used to predict functional epitopes in proteins (Lichtarge *et al*., 1996; Glaser *et al*., 2003). A number of protein sequence databases serve as repositories of vast amounts of data and associated bioinformatics predictions; these can be extremely valuable in inferring function and structure for proteins (e.g., UniProt, InterPro, SMART, and PhyloFacts).

Classification of proteins by sequence signatures

Kay Hofmann
Memorec Biotec GmbH, Köln, Germany

1. Advantages of sequence signatures

Whenever a novel protein sequence moves into the research focus, the question of a sequence-based protein classification arises. Typically, the aim of the classification is the prediction of protein properties, based on information already available for better-characterized members of the same class (Hofmann, 1998). A number of different and sometimes even orthogonal classification systems exist. One of them, referred to as "molecular taxonomy," deals with evolutionary relationships of the protein. Other systems classify proteins by their domain content, biological function, subcellular localization, or other protein properties that can be predicted from the sequence.

The traditional way of classifying an uncharacterized protein starts by running a database search for related sequences. In advantageous situations, this search will uncover convincing sequence similarities to a well-characterized protein, maybe from another species, but possibly also a paralog from the same species as the query protein. In this case, the researcher can speculate that some of the important properties may be shared between the two proteins. This relatively simple method has some shortcomings and also offers some pitfalls. Frequently, the result of a similarity search is not as clear-cut, for example, if multiple significant similarities to proteins of different (or even contradicting) functions are reported. (Attwood, 2000; Hofmann, 1998).

Even an apparently clear similarity situation can be misleading: If a query protein turns out to be closely related to 10 different proteins, all well-characterized protein kinases from different organisms, one is tempted to assume that the query is also a kinase. However, there still is the chance that the similarity between the query and the kinases is confined to a sequence region not including the catalytic domain. In this case, the simple transfer of information would be unwarranted. As many database sequences have obtained their annotation records through fully automated procedures, some of them apparently prone to this kind of mistake, current sequence databases abound with misannotated entries. This unfortunate situation further complicates the protein classification by sequence similarity (Bork and Koonin, 1998).

An obvious way of avoiding this kind of problem is to replace (or at least to augment) the simple sequence-to-sequence comparison with a method based on sequence signatures. A sequence signature aims to be a suitable descriptor for a certain functionality, for example, the function of a protein to act as a kinase. Sequence signatures must be able to store all the information necessary to detect whether a given sequence contains the feature represented by the signature.

2. Types of sequence signatures

As the nature of potentially interesting sequence features can be very diverse, ranging from small protein modification sites to large functional homology domains, there also exist a number of different signature types.

2.1. Signatures based on regular expressions

"Regular expressions" is a concept borrowed from text matching that can be readily applied to sequence searches as well. In the biological context, a regular expression can be viewed as an extension of the widely used consensus sequence representation, where some positions require a particular sequence residue (a strict consensus), while other positions have a more relaxed requirement or no requirement at all. Two examples for easy regular expressions of proteins are given below, one describing a simplified version of the N-linked glycosylation motif and the other one a C-terminal motif for ER-localization:

$$\mathrm{N}-x-[\mathrm{ST}] \quad \text{or} \quad \mathrm{K}-x(0,1)-\mathrm{K}-x-x\rangle$$

The first pattern matches a fixed-length sequence region of three residues, the first one requiring an asparagine (N), the second matched by any residue, while the third being either serine (S) or threonine (T). The second pattern adds two powerful features, a variable-length spacer $x(0,1)$, meaning "either 0 or 1 position are matched by anything" and, also, a provision for anchoring a match to the end of a sequence (indicated here by the angular bracket). Regular expressions are particularly well suited for the description of short sequence stretches, such as modification sites and binding- or targeting motifs. This use of regular expressions has been heralded by the PROSITE database (Bairoch, 1993; *see also* Article 84, **Functionally and structurally relevant residues in PROSITE motif descriptors**, Volume 6), whose syntax has been used in the examples above. More recently, the ELM project (for eukaryotic linear motifs) has started to use regular expressions, augmented by other types of information (Puntervoll *et al*., 2003).

In order to be useful for prediction purposes, a sequence signature must have a certain minimal information content. If very short sequence regions are described, a large proportion of strongly conserved residues is required; otherwise, the pattern would be expected to match many database sequences by chance alone. Many motifs of biological importance are too weakly defined to be useful for database

searches, among them are the glycosylation motif mentioned above and most recognition sites for protein kinases. Even if the information content is too low to tell a relevant sequence from an irrelevant one, those regular expressions can still be useful to find a particular site within a given sequence. Biological motifs largely devoid of invariant positions, but rather defined by a larger region of weak positional preferences, are more easily described by other types of sequence signatures.

2.2. Signatures based on weight matrices

While regular expressions always give a clear yes/no decision, most other sequence signatures use a scoring approach instead, where the score indicates how close the sequence under study comes to the "ideal" motif. If a binary decision is required, those quantitative descriptors must be combined with a threshold score, which indicates whether the match is good enough to be considered real.

The "weight matrix" is a simple version of a quantitative sequence signature (Staden, 1984). A weight matrix is a two-dimensional table that contains scores for each possible residue at each position. In the simplest case, these scores can be obtained by counting how frequently a particular residue is observed at a particular position while analyzing a set of well-established occurrences of the motif. Once a weight matrix is "trained," it can be used to score query sequences. The total score assigned to a sequence or a sequence fragment typically corresponds to the sum of the residue scores over all positions of the weight matrix.

As weight matrices make no provisions for sequence insertions or deletions, they are most useful for describing short- to medium-sized sequence motifs without gaps. In particular, when describing DNA motifs such as transcription factor binding sites, weight matrices have been used very successfully (Stormo, 1988).

2.3. Signatures based on profiles

Sequence profiles, an extension of the original weight matrix concept (Gribskov *et al*., 1987), are more suitable for the description of longer protein motifs or domains, which may contain insertions and deletions. As the weight matrix, a profile is a two-dimensional table of residue scores, and the overall quality of a sequence aligned to a profile is calculated as the sum of all residue scores occurring in that alignment. There are a number of important differences though.

As profiles are geared toward protein comparisons, the residue scores are not just the corresponding residue frequencies but are derived from those frequencies by application of a substitution matrix. As an advantage of this procedure, a profile also contains meaningful score values for residues that have never been observed in the set of "training sequences" used for profile construction. Most useful substitution matrices contain both positive values (for identical residues or conservative substitutions) and negative values (for all other substitutions), with a distinctly negative average. Thus, like a two-sequence comparison by the Smith–Waterman algorithm (Smith and Waterman, 1981), a sequence-to-profile comparison can be run in local mode, that is, not requiring all of the profile to match to the sequence.

Another feature borrowed from Smith–Waterman alignments is the treatment of sequence gaps by applying two specific penalty scores, a more expensive "gap creation penalty" and a cheaper penalty for extending an already existing gap by one residue. In classical two-sequence comparisons, those penalties are uniform throughout the alignment. By contrast, profiles can store different sets of penalties for each position. As profiles are typically derived from preexisting multiple alignments of related sequences, gap penalties can be lowered at profile positions where insertions or deletions are known to occur; they can be raised in profile regions where members of the relevant sequence class are known to align without gaps.

Sequence profiles can be seen as a hybrid between weight matrices and Smith–Waterman sequence comparisons, combining the best of both worlds. The sequence-to-profile score is calculated by a modified version of the dynamic programming algorithm widely used for sequence-to-sequence comparisons. There are a number of different profile methods being used. The original version introduced by Gribskov in 1987 (Gribskov *et al*., 1987) had some restrictions, which are alleviated in the more versatile "generalized profiles" of Bucher *et al*. (1996).

2.4. *Signatures based on HMMs*

In 1994, a particular class of linear Hidden Markov Model (HMM) was introduced as a sequence motif descriptor (Baldi *et al*., 1994; Krogh *et al*., 1994). Conceptually, HMMs are very different from the simpler signature types described above. However, the resulting motif or domain descriptor behaves very similar to a sequence profile. It has even been shown that the most widely used class of HMMs can be transformed into a generalized profile (and back) without any loss of information (Bucher *et al*., 1996). This type of Hidden Markov Model is thus often referred to as "profile-HMM" and forms the basis of several very useful protein domain databases (Eddy, 1998).

An exhaustive explanation of the HMM concept would be beyond the scope of this chapter, but there is an extensive literature on that subject, for example, Eddy (1998). In brief, a profile-HMM can be understood as a kind of "machine" that generates sequences. This machine has a large number of "dials," which must be fine-tuned so that the generated sequences are typical representatives of a given motif class. There are several kinds of components within this machine, some of them having the task of adding a further residue to the sequence (with a particular "dial" adjusting the probability of what residue to create). Other components make decisions whether to switch into an insertion or deletion mode, again associated with a specific parameter indicating the probabilities.

All of the HMM parameters are fine-tuned in a probabilistic fashion by training the HMM with a given set of known instances of the domain or motif to be described. When scoring a query sequence against a trained HMM, the direct result is a probability, indicating how likely it is that this particular sequence would have been generated by the HMM. The absolute value of this probability is meaningless but is typically compared to the probability that this sequence is

generated by a background-HMM, trained to produce a random sequence of the same characteristics as the query sequence. It is the ratio of those probabilities that decides whether a query sequence should be considered as containing the motif described by the trained HMM. The range of applications of profile-HMMs is similar to that of sequence profiles, that is, the description of medium-sized or longer protein domains that may contain gaps.

2.5. Other signatures

In addition to the sequence signatures described above, there are a number of hybrid forms being used, and there also exist some signature types addressing very specific tasks. A protein "block," as introduced by Henikoff and Henikoff (1991), is a particular type of weight matrix that uses the same substitution matrix concept as profiles but does not allow for insertions or deletions. A protein "fingerprint," introduced by Attwood and Beck (1994), is an extension of the "block" approach, where the simultaneous occurrence of multiple blocks in a single sequence is scored, neglecting the distance between the blocks. A signature type specifically addressing the task of defining RNA-motifs is the "stochastic context-free grammar" (SCFG), in particular, its implementation as a "covariance model," which forms the basis of an RNA motif database (Eddy, 2002).

3. Making use of sequence signatures

Sequence signatures have been very successfully applied as comprehensive descriptors of protein motifs and domains. Searching matches to a query sequence in a database of sequence signatures typically yields results that are far easier to interpret than those from a sequence database search. In addition, the more sophisticated signatures, such as generalized profiles and HMMs, are also more sensitive than sequence searches and can detect sequence relationships at very long evolutionary distances (Hofmann, 2000). The main reason for the enhanced sensitivity lies in the additional information on the relative importance of the motif residues that can be stored in a sequence signature. A sequence-to-sequence alignment algorithm cannot tell which regions are important or where gaps can be tolerated easily. A profile or HMM is derived from a multiple alignment and does have access to this kind of information. Obviously, signature databases cannot offer the same degree of coverage as the sequence databases. Nevertheless, there is a large number of signature databases available, many of them described in more detail elsewhere in this book (*see* Article 84, **Functionally and structurally relevant residues in PROSITE motif descriptors**, Volume 6, Article 85, **The PRINTS protein fingerprint database: functional and evolutionary applications**, Volume 6, Article 86, **Pfam: the protein families database**, Volume 6, and others). In particular, the creation of InterPro (*see* Article 83, **InterPro**, Volume 6) as a kind of meta-database has alleviated the need to search a large number of signature databases with different signature types and query interfaces.

Classification of proteins by clustering techniques

Evgenia V. Kriventseva
BASF AG, Ludwigshafen, Germany

1. Introduction

Genome sequencing provides us with an abundance of genes lacking experimentally determined function. To overcome this limitation, Bioinformatics tools are used to generate hypotheses on gene functions. To use just pairwise sequence homology as a hint on gene function can be misleading (Bork and Koonin, 1998). A more reliable basis for functional inference relies on the concept of protein families, collections of proteins with common evolutionary origin. During the past 15 years, different approaches, such as protein-signature recognition and sequence clustering (Kriventseva *et al*., 2001) were developed for the identification of protein families.

Many well-studied protein families contain conserved regions, which can be summarized by a characteristic sequence profile. There are a number of databases storing this kind of protein domain definitions using several different methodologies and a varying degree of biological annotation (see Table 1). PROSITE (*see* Article 84, **Functionally and structurally relevant residues in PROSITE motif descriptors**, Volume 6) is the oldest of the sequence-motif databases that relies on regular expressions and generalized profiles to identify groups of related proteins. Another broadly used approach to model the consensus sequence of amino acids probabilistically is called *HMM* (*Hidden Markov Models*) (Eddy, 1998). This approach has been successfully used in databases like Pfam (*see* Article 86, **Pfam: the protein families database**, Volume 6), SMART (Letunic *et al*., 2004), TIGRrFams (*see* Article 88, **Equivalog protein families in the TIGRFAMs database**, Volume 6), and SUPERFAMILY (Madera *et al*., 2004).

When structural information is available, it is possible to define protein families and domains at the level of their physical shapes, which are more conserved than sequences. The most prominent examples of such databases are CATH (Orengo *et al*., 2003) and SCOP (Andreeva *et al*., 2004). Most of the sequence domain signature databases and structure classification databases are now integrated in InterPro (*see* Article 83, **InterPro**, Volume 6). Although extensive, these collections of protein family and domain descriptors depend on manual curation and are therefore not comprehensive. Protein-clustering techniques complement these efforts in an automated and comprehensive manner. This review will describe the most popular clustering algorithms and databases of clustered proteins.

2. Clustering techniques

Clustering can be defined as a way of identifying a natural grouping of the data. Groups are identified on the basis of distances between elements. In the case of protein classification, the workspace can be represented as a graph whose vertices correspond to the sequences. Vertices may be linked by weighted directional edges. The edges are weighted to represent the degree of similarity between two vertices calculated as a pairwise similarity scores between sequences. Strongly connected sets of vertices should then represent clusters of related proteins in sequence space (Tatusov *et al*., 1997).

There are different mathematical solutions on how to classify objects into groups or clusters, optimizing similarity among elements inside a cluster or dissimilarity among different clusters. The latter approach is applicable if the final number of clusters could be estimated in advance (i.e., k-mean clustering). Since the number of protein families in a set is usually not known in advance, the agglomerative hierarchical clustering procedures are better suited for classifying protein sequences into families, providing snapshots on different levels of specificity.

A hierarchical clustering procedure starts with considering elements in the input set as singleton clusters. Then the procedure merges interactively similar clusters and, using different similarity levels, forms the hierarchy of clusters. This procedure results in a tree-like structure, where sibling clusters partition their parent cluster. The hierarchical clustering problem is essentially equivalent to the reconstruction of evolutionary trees also known as "phylogeny".

There are various formulations of the target function for the hierarchical clustering favoring different topologies of the resulting clusters, for example, the single-linkage algorithm produces clusters of linear topology where an element should be similar to at least one other element in the cluster, while complete linkage performs better on compact clusters where all elements of a cluster are similar to each other. These methods produce nonoverlapping clusters; one protein can belong at a certain similarity level to only one group. Unfortunately, nature is more complex and multidomain proteins cannot be correctly classified in this way. A few attempts have been made to redefine the problem to allow overlapping solutions (e.g., Gaussian mixtures models (Dubey *et al*., 2004), fuzzy k-mean (Sarkar and Leong, 2001), etc.).

There are two main complications in automatic clustering procedures: different protein families have different levels of sequence similarity and multidomain proteins pull together proteins with different domains. Hierarchical clustering, defining clusters at different levels of sequence similarity, is one of the approaches to solve these problems. For example, the CluSTr (Kriventseva *et al*., 2003) methodology works with a prior defined set of cutoffs, whereas the SYSTERS (Krause *et al*., 2002) and SL-KL (Kawaji *et al*., 2004) methods automatically select different levels of protein similarity. The following section will show in more details how different approaches try to address these problems.

Single-linkage clustering, also known as *Nearest Neighbor Clustering* (Sokal and Rohlf, 1995), can be described as follows: if an object A, in our case a protein A, is similar to a protein B and the protein B is similar to a protein C then all three proteins are clustered together. This is a simple clustering algorithm, where the results are easy to interpret and are well corresponding to the underlying evolutionary model of protein divergence from a common ancestor. For these reasons, the algorithm was used in SYSTERS (Krause *et al*., 2002), CluSTr (Kriventseva *et al*., 2003), GeneRage (Enright and Ouzounis, 2000), and BLASTClust (**ftp://ftp.ncbi.nlm.nih.gov/blast/**; BLASTClust is a part of the NCBI BLAST package, performing BLAST comparisons followed by single-linkage clustering).

Complete linkage clustering, also known as *Furthest Neighbor Clustering* (Sokal and Rohlf, 1995), can be described as follows: two objects A and B belong to the same cluster if the similarity between them is greater than a chosen threshold. With the complete linkage clustering, all objects in a cluster are similar to each other. The complete linkage strategy produces compact clusters without chaining.

The average linkage clustering or "centroid sorting method" used by the ProtoNet project (Sasson *et al*., 2003) can be seen as an intermediate between single and complete linkage clustering, picking out more homogeneous clusters than those obtained by the single-linkage method.

A few new clustering algorithms were brought to Bioinformatics recently, for example, the MCL (Van Dogen 2000 thesis) clustering based on probabilistic flow simulation in a defined similarity matrix. Although interesting, the method yields poorly interpretable results. Another method proposed by Abascal and Valencia (Abascal and Valencia, 2003) adopts a normalization cut (Ncut) algorithm (Shi and Malik, 1997). In comparison to other methods, this procedure focuses on the space surrounding a given protein by analyzing only local sequence relations. A method inspired by the physical properties of ferromagnetics called superparamagnetic clustering (Blatt *et al*., 1996) is based on partition of "spin–spin" correlations defined on short-range interactions rather than distances themselves.

3. Current protein-clustering approaches

There are two main approaches for protein classification: the comparison of full-length sequences and the comparison of just parts of sequences, the protein domains. ProDom (Servant *et al*., 2002), SBASE (Vlahovicek *et al*., 2003), DOMO (Gracy and Argos, 1998), and Picasso (Heger and Holm, 2001) provide an automated partition of protein sequences into protein domains based on common regions in sequence alignments. The ProDom approach considers the shortest full-length sequence in a database as a single-domain protein and uses PSI-BLAST (Altschul and Koonin, 1998) to find homologous sequences, which are then clustered in the same ProDom entry. In the Picasso approach, clusters are defined on the basis of multiple overlaps in aligned sequences using all-against-all BLAST comparison. For each such multiple alignment, a profile is created, which is used for the further unification of the clusters by profile–profile comparison.

A group of protein family–cluster databases is connected to the Protein Information Resource (PIR) (McGarvey *et al*., 2000). PIR-ALN is a database of protein sequence alignments derived from sequences and annotations in the PIR protein sequence database. Information about PIR protein families, protein superfamilies, and homology domains can be found in ProtFam database hosting the alignments of all PIR superfamilies and homology domains (Mewes *et al*., 2002). iProClass is a recent extension of ProClass (Wu *et al*., 2004) classifying proteins using PIR superfamilies and PROSITE motifs. PIR-ASDB is an Annotation and Similarity DataBase (McGarvey *et al*., 2000) containing precomputed sequence neighbors of all PIR-PSD entries based on all-against-all FASTA searches (Pearson, 1990).

CluSTr (Kriventseva *et al*., 2003), SYSTERS (Krause *et al*., 2002), ProtoMap (Yona *et al*., 2000), and ProtoNet (Sasson *et al*., 2003) classify proteins on the basis of full-length sequence comparisons and provide a hierarchical organization of protein clusters by performing analysis at different levels of sequence similarity. The SYSTERS approach is based on all-against-all gapped BLAST comparison followed by single-linkage clustering. To avoid arbitrarily chosen static thresholds, the procedure defines superfamilies at the level corresponding to the largest increase in a cluster size by traversing the merging tree in the hierarchical single-linkage procedure. Each of the superfamilies is further cut into family clusters by detecting weak connections.

ProtoMap uses a combination of Smith–Waterman (Smith and Waterman, 1981), FASTA (Pearson, 1990), and BLAST (Altschul and Koonin, 1998) searches. In the first classification step, confident cores of clusters are determined at high stringency cutoff. The resulting classes are then merged to form bigger and more diverse clusters by considering weaker, less significant similarities. The procedure is repeated at different levels of similarity. The ProtoNet project builds on the work started in the ProtoMap project. It uses gapped BLAST to calculate similarities, and then applies an average linkage clustering algorithm with three different metrics to merge proteins into clusters: harmonic, geometric, and arithmetic averages of protein distances.

In comparison to the algorithms described above, the CluSTr approach is based on rigorous Smith–Waterman comparisons. To estimate the statistical significance of raw Smith–Waterman scores, a Monte-Carlo simulation (Comet *et al*., 1999) resulting in a Z-score is used. This allows incremental updating of data, thus avoiding time-consuming recalculations. The clusters are built using a single-linkage algorithm at different levels of protein similarity, allowing users to choose different levels of confidence.

The GeneRage (Enright and Ouzounis, 2000) algorithm starts with BLAST all-against-all comparisons, resulting in a binary matrix of similarities. The matrix is then analyzed for identifying multidomain proteins. This is achieved through iterative processing of the matrix elements with successive rounds of Smith–Waterman dynamic programming alignments. Single-linkage clustering is then applied to build the clusters. Clusters containing multidomain families are split into their constituents.

TRIBE-MCL (Enright *et al*., 2002) uses the MCL clustering algorithm. The approach is built on the basis of all-against-all BLAST alignments with following averaging of the similarity scores to make the distance matrix symmetric. Then Markov Clustering is performed by simulating a random walk within a similarity graph. This is done by taking iteratively the power of a matrix, called *expansion* (i.e., matrix squaring), followed by entry-wise powers, called *inflation*. Expansion causes stochastic flow to dissipate within clusters, whereas inflation eliminates flow between different clusters.

The CLICK (CLuster Identification via Connectivity Kernels) (Sharan *et al*., 2003) clustering algorithm was originally developed for the grouping of genes with similar expression patterns into clusters. The algorithm identifies kernels in the similarity graph, defined as highly interconnected subgraphs. Several heuristic procedures are then used to expand the kernels into the full clustering. CLICK has been implemented and tested on a variety of biological datasets, ranging from gene expression, cDNA oligo-fingerprinting to protein sequence similarity.

4. Conclusions

Very recently some major advances in protein-cluster analysis have been made. The exponentially increasing volume of functionally uncharacterized sequences drove the research. While sequence signature recognition methods developed through expert analysis of protein families and domains gain more and more importance,

they need to be complemented by comprehensive clustering techniques. Although the currently available resources have already provided a starting point for in-depth studies of uncharacterized protein families and domains, further work is required to ensure that more of the biological properties of data are recognized correctly.

Getting the most out of protein family classification resources

Nicola J. Mulder
European Bioinformatics Institute, Cambridge, UK

1. Introduction

Protein family classification resources have been discussed in the previous chapters. They include the following protein signature and protein clustering databases: PROSITE (*see* Article 84, **Functionally and structurally relevant residues in PROSITE motif descriptors**, Volume 6) (Hulo *et al*., 2004), PRINTS (*see* Article 85, **The PRINTS protein fingerprint database: functional and evolutionary applications**, Volume 6) (Attwood *et al*., 2003), Pfam (*see* Article 86, **Pfam: the protein families database**, Volume 6) (Bateman *et al*., 2004), SMART (Letunic *et al*., 2004), TIGRFAMs (*see* Article 88, **Equivalog protein families in the TIGRFAMs database**, Volume 6) (Haft *et al*., 2003), PIR SuperFamily (*see* Article 87, **The PIR SuperFamily (PIRSF) classification system**, Volume 6) (Wu *et al*., 2004), SUPERFAMILY (Madera *et al*., 2004), ProDom (Corpet *et al*., 2000), and CluSTr (Kriventseva *et al*., 2003). These databases are automatically derived with manual input, in most cases, and are designed for predicting protein family classification for new and existing protein sequences. SCOP (Andreeva *et al*., 2004) and CATH (Orengo *et al*., 2003) classify protein structures, and Merops (Rawlings *et al*., 2004), Transport Classification (Busch and Saier, 2003), and so on, are specialized protein family resources. The former are based on protein 3D structures data deposited in the Protein Data Bank (PDB; Westbrook *et al*., 2003), while the latter are curated databases developed by experts in a particular protein family. These are useful resources for describing the structural or specialized families, and can be viewed via their web pages (see Table 1). They will not be discussed in this article.

All of the aforementioned resources have their individual websites and databases available for searching, and are intuitive to use. Some of them are integrated into InterPro, which serves the data and software from a single source, and thus makes using the individual data and software quick and easy to access. All of them are represented in SRS (sequence retrieval system; Zdobnov *et al*., 2002), which provides an interface for simple and complex queries and facilitates linking between results and new data. This article demonstrates how to access and utilize the protein family classification data and tools using InterPro (*see* Article 83, **InterPro**,

Volume 6) as an example. InterPro consists of entries containing signatures that describe the same set of proteins. Entries that are subsets of others are related to each other as parent/child (family and subfamily) or contains/found in (domain composition) relationships. The goal of InterPro is the classification of proteins into families.

2. Protein sequence classification using InterProScan

A query protein sequence may be run against all the protein signatures in InterPro to identify protein domains or diagnostic features of protein families. The sequence-based search, InterProScan, uses tools provided by the member databases. Sequences can be submitted through a web interface at **http://www.ebi.ac.uk/interpro/InterProScan** and results of hits can be obtained

in InterPro in both a graphical and tabular view. The results from all submissions, including interactive searches, are also received by email that provides the XML formatted results and a link to the HTML output. A mail server is available for sequence searches at interproscan@ebi.ac.uk. The mail server and web server InterProScan are linked to SRS (Zdobnov *et al.*, 2002), which indexes the InterPro matches and data XML files. The advantage of this is the access to additional features in SRS.

2.1. Protocol

2.1.1. Requirements

Workstation connected to the Internet, email program, and web browser.

2.1.2. Steps

1. Open the InterProScan sequence search page: **http://www.ebi.ac.uk/InterProScan/**.
2. Paste your sequence into the box in any format or upload your sequence from a file using the "upload file" button. Enter your email address in the appropriate box (this is required in case the search takes too long and times out).
3. Select PROTEIN or DNA depending on what type of sequence you submit. If it is the latter, you can select your translation table.
4. Press "Submit Job" button to proceed with the search.
5. The results are returned in a graphical format, click on "Table View" button to get the results in a tabular format.
6. Follow the link to the InterPro entries in the database by clicking on the InterPro image (clicking on the SRS image goes to the entry as displayed in SRS), and retrieve further information on the families in question. From the entry view, a user can determine if a relationship exists between the entries matched. If a parent/child relationship exists, click on the "Tree" button to see the hierarchical family tree.

2.1.3. Results

The results (Figure 1a) display matches to the InterPro member database signatures and the corresponding InterPro entries. The table view (Figure 1b) shows the positions of the signatures within the sequence, and shows the entry relationships: parent/child or contains/found in, and Gene Ontology (GO, The Gene Ontology Consortium, 2001) terms mapped to the entries hit. In some cases, there may be matches to signatures that have no corresponding InterPro entry, which are usually ProDom domains that will not be integrated. They may, however, provide additional information for the user, and so are maintained in the InterProScan data files. The results should give the user an idea of the family and domain composition of the query protein sequence. If the entries matched are mapped to GO terms, this implies that the query protein can be mapped to these GO terms, thus providing more functional annotation.

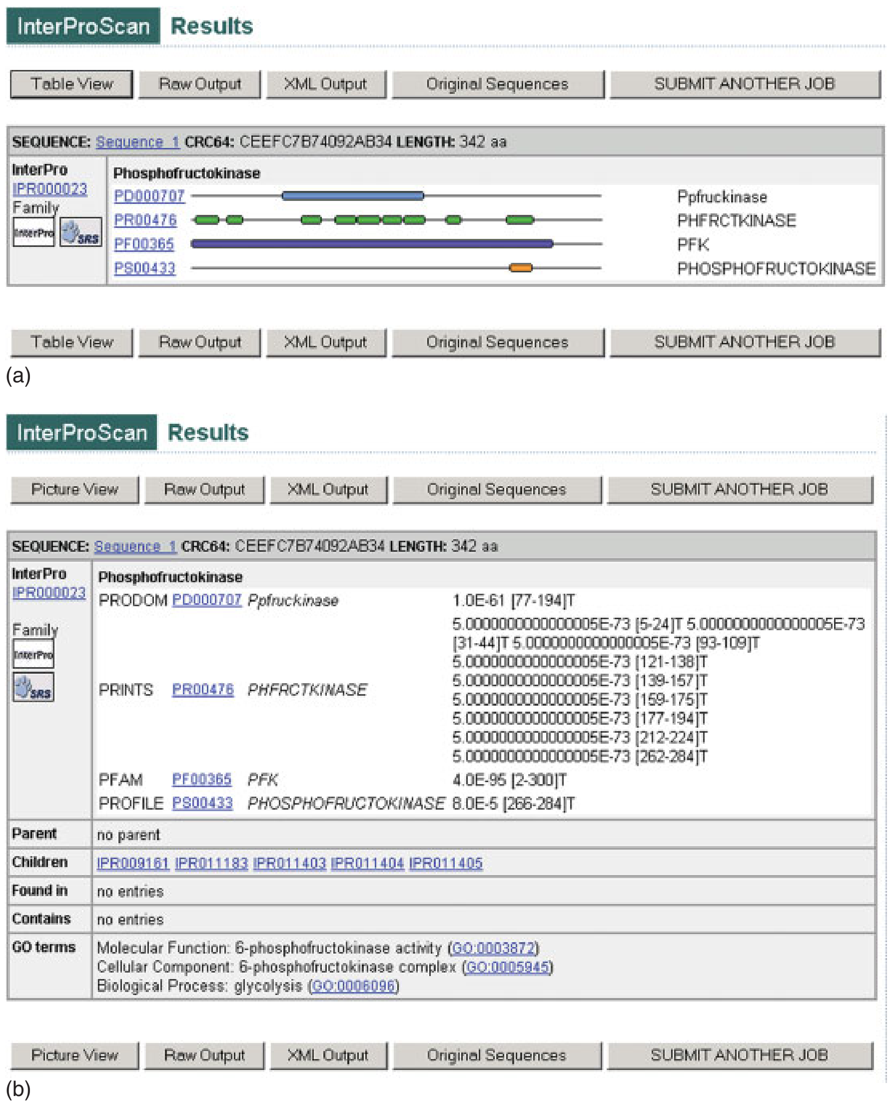

Figure 1 Example of a sequence search result from InterProScan. (a) Graphical view and (b) table view showing entry relationships and GO terms. Links to the original sequence(s) submitted or other formats are provided on each results page

3. Searching InterPro

3.1. InterPro web server

The InterPro web server provides a simple text search tool, as well as a more complex SRS search tool. In the former, it is possible to search entries, in which InterPro fields are searched, find protein matches, where a protein ID or

accession number is the input, and go directly to an InterPro entry by searching for an InterPro accession number. The SRS-based query form facilitates searching based on one field and term in InterPro and one in the protein entries. The output format is selectable. Both search options allow a user to search InterPro on the basis of their terms. In order to browse entries, the InterPro home page (**http://www.ebi.ac.uk/interpro/**) has links to lists of all entries of each type. The lists display the entry names and accession numbers linked to the entries.

3.2. Protocol

3.2.1. Requirements

Workstation connected to the Internet and web browser.

3.2.2. Steps

1. Open the InterPro text search page: **http://www.ebi.ac.uk/interpro/search.html**.
2. To view the InterPro matches for a known protein sequence from UniProt (Apweiler *et al*., 2004), paste a protein accession number in the search box and choose "Find protein matches".
3. Query the database for your protein family or domain of interest by putting the relevant text in the search box and choose "Search entries".
4. Click on one of the entries in the results and view the InterPro entry. In the entry, click on "Table: For all matching proteins " in the first field to list all proteins matching the entry.

3.2.3. Results

The search results are provided in different formats, depending on the output requested. Either way, however, it is possible to reach the relevant InterPro entries. Each entry has the following information in it: protein matches, signatures, relationships, GO terms, abstract, example list, taxonomy field, structural or database links, and publications. The annotation provides a lot of information about the proteins or the search term(s) in question.

3.3. InterPro through SRS

SRS is a system for retrieval of data from a variety of sources. It indexes a number of databases with the ability to launch applications from search results. Results can also be linked to other databases, which allows for very complex queries. InterPro is indexed in SRS and InterProScan is one of the applications available. A minor difference between searching InterPro in SRS and via the InterPro web server is that the former uses the InterPro XML file and the latter is served directly out of the database. At new releases, the data is synchronized.

3.4. Protocol

3.4.1. Requirements

Workstation connected to the Internet and web browser.

3.4.2. Steps

1. Go to SRS at **http://srs.ebi.ac.uk**.
2. Click on "library" tab on the top menu to get to the library page.
3. To begin, choose a "library", for example, InterPro, you would like to search. If InterPro is not visible on the page, you may need to expand the relevant heading (Protein function, structure and interaction databases). Select InterPro as the library, enter a term in the search box at the top and click "Quick Search".
4. Alternatively, select the library and choose Standard or Extended Query form on the left. In the "Standard Query form", four different search terms can be entered, while the "Extended Query form" allows a user to search all fields available in the library.
5. Once you have the search results, go to the "Results" link at the top of the page. Select the required result, and on the "view" scrollbar you can choose a view for them. The results can be ordered by a chosen field, and applications can be launched from them.
6. It is possible to customize a view for your results. Go to "Views" at the top of the page and follow the instructions in the SRS help pages.

3.4.3. Results

The SRS search tools produce the results in the user-specified format. If multiple searches are performed, chosen results sets can be combined on the "results" page. Results can also be linked to other databases, for example, InterPro results can be linked to GO to find the associated terms.

4. Troubleshooting

InterProScan is based on scanning methods native to the InterPro member databases, so all data and applications rely on that provided by these databases. It is distributed with preconfigured method cutoffs recommended by the member database experts and that are believed to report relevant matches.

If the HTML link to InterProScan results returns an error message, it may be that either the web server is inaccessible at the time or that the results are more than 24-hours old, after which time they are removed. In these cases, it is necessary to run the sequence through InterProScan again. For any problems, please email interhelp@ebi.ac.uk.

If no results are obtained, it may be that the sequence is too short, but it is more likely that the member databases have not yet created a protein signature diagnostic for that protein family. Currently, signatures in InterPro cover over

80% of all proteins in UniProt, and the remaining proteins are less likely to have signatures since they belong to very small families. If no results are found, it may be worth running the sequence at the ProDom or Pfam websites. ProDom groups all the nonfragment sequences in UniProt into more than 150 000 families and has therefore almost complete coverage of protein sequence space. Only the bigger, "quality" families in ProDom are integrated into InterPro. A potential hit at the ProDom website that was not found by InterProScan will not provide much annotation or biological information but will give an idea of any related proteins.

Pfam has an automatic supplement to the curated HMMs known as PfamB, which is based on ProDom and provides another means of finding related proteins. If still no information is derived from these searches for the query sequence, it may be worth trying the protein structure classification databases SCOP (Andreeva *et al*., 2004) and CATH (Orengo *et al*., 2003).

5. Discussion

Elucidation of protein function is important not only in genomics but also for individual researchers identifying new genes. Protein family classification resources provide useful tools for achieving this. These tools are available via the Web and should be utilized alone, or more importantly, in combination, for analysis of uncharacterized protein sequences. InterPro and SRS facilitate this and give the user significant options for selection of inputs and outputs to narrow down their searches and save a lot of valuable time. This article has described the main approaches of searching InterPro through the InterPro web server and through SRS as an example of an extremely useful family classification resource. Other databases are also available at EBI through SRS using similar access protocols, and those databases not available at EBI through SRS or other search interfaces are usually available via their own web servers. The Web is awash with data and resources for the scientific community to explore protein functional classification methods.

Introductory Review

What use is a protein structure?

Simon E. V. Phillips
University of Leeds, Leeds, UK

1. Introduction

Understanding biological organisms in terms of the underlying molecular processes is the main aim of molecular biology. Biological molecules obey the same laws of physics and chemistry as other simpler molecules, so it should be possible to understand how cells and organisms work in molecular detail. Complexity is a defining feature of biological macromolecules, manifested in terms of information content, as in DNA sequence, and structure, as in proteins (and some RNA). Proteins are the major workhorses in the system, and their highly complex three-dimensional structures allow high-fidelity molecular recognition between the thousands of components that must operate together. In order to understand fully how such systems work, it is essential to have accurate, atomic resolution structures for the components. This requires X-ray crystallography (*see* Article 104, **X-ray crystallography**, Volume 6) and NMR (*see* Article 105, **NMR**, Volume 6) experiments since structure prediction from gene sequence, while advancing rapidly, is currently insufficiently reliable and accurate.

While some proteins, such as collagen fibers in tendon, simply contribute to the overall macroscopic structure of an organism, the majority are active components. Enzymes catalyze chemical reactions, both in metabolism and signaling, receptors recognize signals and process them, membrane proteins pass molecules and/or signals across membranes, muscle proteins form linear motors that drive motion, photosynthetic proteins transduce light energy into chemical energy, transport proteins carry cargo molecules, and immune system proteins search for, and destroy, foreign molecules. It is a natural human aspiration to understand these systems, both in healthy and diseased states, but this knowledge also gives us the power to intervene. This could be for therapy, such as in the design of new drugs, or by taking proteins out of their natural system and engineering them for other uses in vitro.

When Dorothy Crowfoot (later Hodgkin) and Max Perutz (*see* Article 95, **History and future of X-ray structure determination**, Volume 6) set out, in the 1930s, to determine the structures of insulin and hemoglobin respectively, they did so because of their fascination with the problem. They also recognized that understanding these protein structures was likely to have implications for medicine. While the relevance of insulin to diabetes was already clear at the time, it was some years later when Linus Pauling proposed that the inherited disease sickle-cell

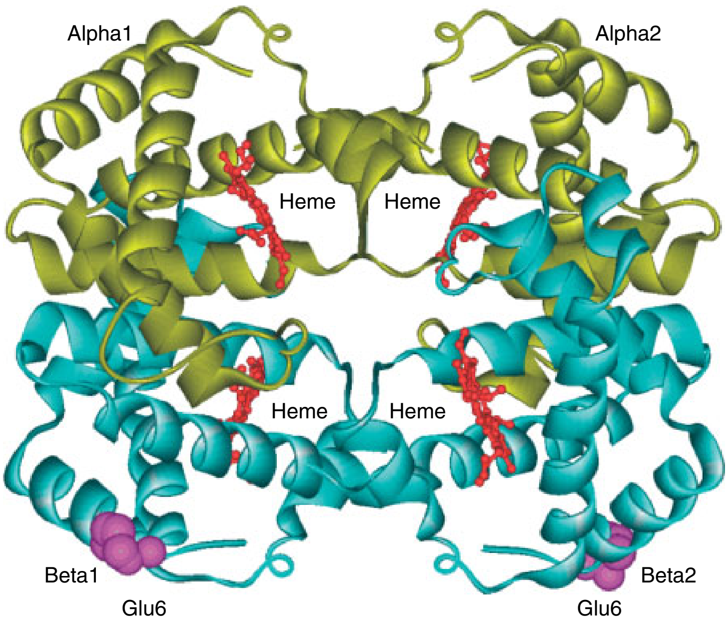

Figure 1 Human deoxyhemoglobin tetramer (HbA), with the protein chains shown as ribbons and the heme groups in red ball and stick representation. Alpha chains are gold and beta chains cyan. Oxygen binding to the heme groups causes a rotation of the alpha1/beta1 dimer relative to alpha2/beta2. The site of the mutation to HbS is shown with Glu6 colored magenta in space-filling representation. Coordinates from Protein Data Bank (PDB – **http://www.pdb.org**) code 4hhb

anemia was caused by a defect in the hemoglobin molecule, and was therefore a "molecular disease" (Pauling *et al*., 1949). When Perutz finally determined the crystal structure of deoxyhemoglobin, and built an atomic model in 1968, the result was stunning in its beauty and complexity, but he expressed disappointment that how it worked in cooperative oxygen transport was not immediately apparent from looking at its structure (Figure 1). The later crystal structure of the oxy- form showed large changes in quaternary structure (arrangement of the four subunits) that was related to the observed cooperativity and triggered by small structural changes when oxygen binds to the heme groups. It was clear that, although knowledge of the three-dimensional structure is essential, it is also critical to combine information on function gained from other studies.

Structural studies are vital to guide functional studies, and the two proceed in a symbiotic relationship (for an early account of hemoglobin structure and function see Perutz, 1978). In the case of insulin, where the structure in the crystal is a hexamer, the critical discovery came when the regions contacting the insulin receptor were identified and it became clear that the active form was the free monomer. Pauling's prediction of defective hemoglobin (HbS) in sickle-cell anemia could now be interpreted in structural terms, as it was known that HbS differs from normal hemoglobin (HbA) in that the glutamate residue at position 6 of the ß-chain has been mutated to valine (Figure 1). The change from a charged to a hydrophobic residue gives rise to an extra hydrophobic patch on the surface, which tends to stick

to hydrophobic patches on other HbS molecules. HbA is very soluble, and present in the red cells at very high concentrations, but it does not restrict the cells' flexibility and ability to squeeze through the finest capillaries of the vascular system. HbS molecules, on the other hand, when in the deoxy- form, tend to stick together via their extra hydrophobic patches to form stiff fibers that cause the cells to become inflexible and jam in the capillaries, resulting in the painful and dangerous crises of sickle-cell disease. The crystal structure of HbS, together with electron microscopic studies of the fibers, revealed the molecular basis of the disease, and it was possible to consider the prospect of designing a treatment for the disease at the molecular level. We now know of many diseases caused by such point mutations. Another dramatic early example was the observation that a common mutation in human tumor cells is in the ras p21 protein, involved in signaling pathways, where inspection of the crystal structure shows that the change lies in a protein loop responsible for binding part of the substrate guanosine triphosphate (GTP).

The cases above show how knowledge of the structure of a protein is essential to understanding its function (or malfunction), but how can that knowledge and understanding be applied to modify its behavior?

2. Structure-based drug design

Much of the success of modern medicine stems from the availability of a wide range of drugs. Until recently, many of these had their origins in traditional remedies from which pharmaceutical companies identified and produced the active agents, as well as chance observations such as penicillin, and random screening of large numbers of natural products. Most drugs are effective because they bind to a specific receptor, often (but not always) a protein molecule, and modify or block its function. Drugs are generally organic molecules with molecular weights of up to a few hundred, relatively small compared to proteins but large enough to have complex shapes and chemical characteristics. They bind to their target proteins with high affinity and specificity, typically in clefts whose shapes and chemical characteristics (charge, hydrophobicity, hydrogen bonding) are accurately complementary to those of the drug. Since the physical principles of the noncovalent interactions between the drug and the protein are well understood, it is possible to use computer graphics modeling to design small molecules that should bind to a site in a given protein structure. Such a procedure clearly depends on knowledge of the structure of the target protein, and has become known as structure-based drug design. True de novo design of a drug remains challenging since it requires accurate predictions of binding energies, and these are complicated by protein dynamics, solvent, and entropic effects. The method is, however, very powerful, where some experimentally determined structures are also known for complexes of the protein with putative drug molecules that may not bind very tightly but can serve as "lead" compounds. Such lead compounds can sometimes be initially identified by virtual screening using a computer, where the known structure of a protein drug target can be tested against huge libraries of small molecules in a search for possible binding partners. Computer graphics is then used to improve the design, a new molecule is synthesized, the structure determined of its complex with the

protein, and its affinity measured. The cycle can be continued until the tight-binding, specific compounds are found that can go to the next stages of drug testing. This has become standard practice in the pharmaceutical industry, and the methodology is also applicable in the design of herbicides and pesticides. The whole procedure is, however, critically dependent on the availability of accurate, three-dimensional structures of the protein targets, that must be determined experimentally and cannot be simply predicted from gene sequences.

This has led to the structure determination of many proteins known to be drug targets, as well as those predicted to be new targets from genome information. In the case of some traditional drugs, the target protein structures have been determined in an effort to make improvements to the drug design. For instance, this is the case for aspirin, where structures are known for its targets cyclooxygenase and phospholipase-A2, and their complexes with various aspirin derivatives. Perhaps more interesting are drugs designed more recently on the basis of target protein structures, such at those aimed at human immune deficiency virus (HIV) protease and reverse transcriptase, influenza neuraminidase, and human kinases. Influenza is a dangerous virus, where antigenic variation renders vaccination difficult. Neuraminidase (NA) is one of two major proteins on the influenza virus surface. It cleaves sialaic acid from cell surface receptors, probably facilitating release of progeny virions, and its inhibition reduces the severity of the infection. Following the determination of the crystal structure of the globular catalytic head domain of NA (Colman *et al*., 1983), the active site was used as a design target for inhibitors, leading to one of the first cases of true structure-based design. Zanamavir (Relenza^{TM}) is now licensed as an anti-influenza drug, and the crystal structure of its complex with NA is shown in Figure 2. Protein kinases are major targets in cancer therapy, as they are critical to cellular signaling systems (e.g., in differentiation and proliferation) and there are several hundred different ones in a typical cell. Kinases are related to each other, but have sufficient differences to allow design of drugs that target some of them selectively. In chronic myelogenous leukemia (CML), a chromosome translocation occurs, generating a novel Ab1 tyrosine kinase with

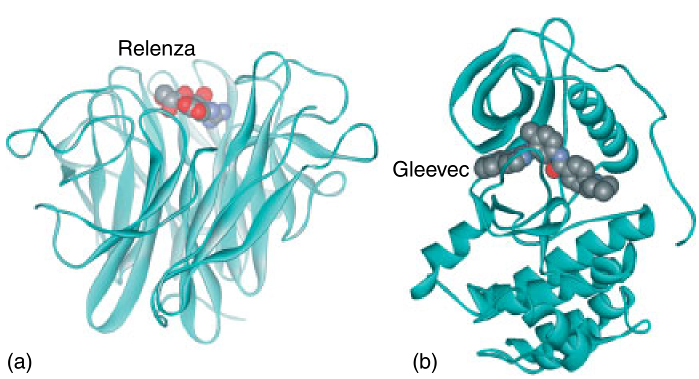

Figure 2 Drug binding to proteins (a) Zanamavir/Relenza^{TM} bound to influenza neuraminidase (PDB code 1a4g) (b) ST571/Gleevec/Glivec^{TM} bound to c-Kit kinase (PDB code 1t46). Drug molecules are shown as space-filling representations in CPK colors

enhanced activity that is a target for intervention. A structure-based design exercise, based on several kinase structures, yielded a compound (STI571) that potently inhibits Ab1, c-Kit kinase, and platelet-derived growth factor receptor (PDGFR), but not other kinases. This has been licensed as the drug Gleevec/Glivec^{TM}, which has shown high activity against CML. Figure 2 shows the crystal structure of Gleevec/Glivec^{TM} bound to the c-Kit kinase.

Many targets for drug intervention, however, are complex protein–protein interactions in signaling pathways or, indeed, in Pauling's original molecular disease, sickle-cell anemia. Drug design is more challenging in these cases, although many structures are known, since most protein–protein interfaces lack the clefts necessary to bind small drug molecules tightly. This is an area of intense research, but progress is slow and no simple cure has yet been found for sickle-cell disease.

3. Protein engineering

While drug design remains the most widespread practical use of protein structures, the ability to use site-directed mutagenesis to engineer modified proteins has resulted in the design of novel proteins for therapeutic and other uses. The most widespread use of enzymes is in "biological" washing powders and some industrial processes. The obvious target for protein engineering here is in improving the stability of the enzymes, especially at higher temperatures. Protein structures are used to guide mutations that confer stability, and obvious alterations include adding additional disulfide bridges or removing long, flexible loops. Other industrial targets include improving stability of useful enzymes in organic solvents. Enzymes are increasingly used in industrial synthesis of small organic molecules with sufficient complexity that chemical synthesis results in mixtures of stereoisomers. Enzymes, on the other hand, are stereospecific, and can synthesize complex molecules, such as those needed to make drugs, as single isomers. It is often the case, however, that no specific enzyme exists for the required synthesis, but it is possible to use knowledge of the protein structure to aid in the design of an engineered enzyme with a more suitable product.

Therapeutic uses of protein engineering based on structural knowledge include the reengineering of insulin and human growth hormone to increase their potency. Knowledge of the hormone structure, and its interaction with the receptor, are important in the design. For instance, normal human insulin exists as a hexamer, but the free monomer is the active species, so the protein was engineered to reduce its tendency to form hexamers by mutating the interfaces between subunits, resulting in a more effective hormone for treatment of diabetes. A major area for protein redesign based on known structures is in the therapeutic uses of antibodies. For instance, antibodies that target antigens on human tumor cells can be raised in rats, but they are of limited use. If administered to a patient, there is some remission of the disease, but the rat antibodies are foreign proteins, so the patient's own immune response soon targets them and reduces their effectiveness. The structure determinations of many antibodies, and especially of their complexes with protein antigens (e.g., Amit *et al*., 1986; Figure 3), showed that only a limited number of amino acid

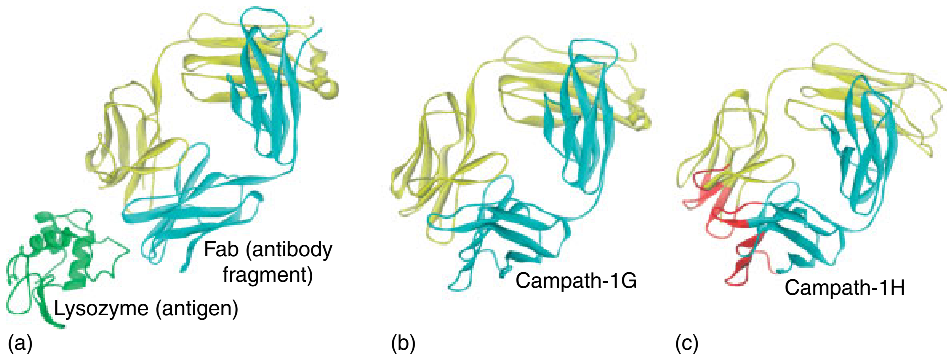

Figure 3 Structure of Fab fragments of antibodies, with the light chains gold and heavy chains cyan. (a) Mouse antilysozyme antibody D1.3 complexed to its antigen. Note the only regions in contact with lysozyme are the CDR loops (PDB code 1fdl). (b) Rat CAMPATH-1G antibody before humanization (PDB code 1bfo). (c) Human CAMPATH1-H antibody with the CDR loops grafted from CAMPATH1-G shown in red (PDB code 1bey)

residues in the six complementarity determining loops (CDRs) of the antibody actually interact with its target antigen. The rest of the antibody molecule simply acts as a constant framework to support the CDRs. This led to the design of "humanized" antibodies, where the specific CDRs of a therapeutic rat antibody were grafted by protein engineering on to the framework of a human antibody, guided by the known structures. In the case of a rat antibody, CAMPATH1-G (Figure 3), that targets human lymphocytes and can be used to treat a number of autoimmune diseases, a humanized version was prepared, CAMPATH1-H (Figure 3), that provided extended remission for patients (Riechmann *et al*., 1988) by evading their immune responses.

4. Protein assemblies and molecular machines

Many of the current uses of protein structures relate to relatively simple systems, but it is clear that most proteins in higher cells act as components of larger complexes. Some of these constitute true molecular machines, such as linear motors in muscle fibers and rotary motors in the ATPase or the bacterial flagellum. Viruses and bacteriophages often have elaborate machinery for entering cells and the photosynthetic complexes in plants contain multiple components that act together to convert light to chemical or electrical energy. Structures are now becoming available for such complexes (*see* Article 100, **Large complexes and molecular machines by electron microscopy**, Volume 6), with the possible opportunity of reengineering them for specific purposes, such as the clean conversion of solar energy or the construction of nanoscale molecular devices. The uses of protein structures are still in their infancy.

Introductory Review

History and future of X-ray structure determination

Joachim Jaeger and Caitriona Dennis
Center for Medical Science, Wadsworth Center, NYS DOH, Albany, NY, USA

1. Early history (1910–1940)

Single crystal X-ray diffraction originated in Germany at the beginning of the twentieth century. Von Laue and colleagues conducted the first diffraction experiments on rock salt and other alkali halides by shining X-radiation, discovered by Roentgen in 1895, onto the crystalline samples (Figure 1). These studies and his mathematical formulation of single crystal X-ray diffraction earned Von Laue the Nobel Prize for Physics in 1914. Independently, W. L. Bragg and W. H. Bragg carried out similar X-ray studies in Leeds, England, where they found that the diffraction phenomenon could be treated – mathematically – as a reflection by successive parallel planes passing through crystal lattice points.

According to both Laue and Bragg, scattered intensities arising from crystals result in sharply ordered diffraction maxima (diffraction spots). The incident beam approaching the lattice plane at an angle θ is being reflected from that plane at an equal angle ("Glanzwinkel"). Laue discovered that the conditions for observing a maximum in diffracted intensities require that the path difference between reflected beams from adjacent lattice planes be an integral number of wavelengths ($h = \mathbf{S}\ a$, $k = \mathbf{S}\ b$, or $l = \mathbf{S}\ c$). Incorporating Bragg's mathematical equation, the distance between lattice planes could be defined as $d = 1/|S|$ and $|S| = 2|\sin\theta|/\lambda$. Thus, it followed that $n\lambda = 2d\sin\theta$, known as Bragg's Law. The Braggs (father and son) were awarded the Nobel Prize for Physics in 1915.

During the 1920s and 1930s, the focus of diffraction studies shifted to more complex systems such as macromolecular fibers and protein crystals. In Leeds, W. T. Astbury and coworkers pioneered structural studies on large fibrous proteins such as hair, wool, and quills and on DNA fibers. After taking the first fiber diffraction images of DNA, he correctly predicted the overall dimensions of the molecule and found that the nucleotide bases were stacked at intervals of 3.3 Å perpendicular to its long axis. It was left, however, to Watson and Crick to later elucidate the detailed atomic structure of the DNA double helix.

The problems encountered in the early days of macromolecular crystallography related to the fact that biological matter interacts only weakly with electromagnetic radiation as the sample is not densely packed with electrons. Proteins and nucleic

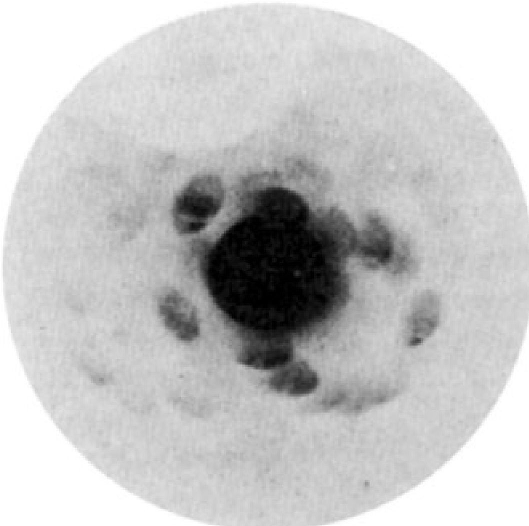

Figure 1 First diffraction pattern from NaCl crystals recorded by Von Laue and colleagues

acid typically consist of light elements such as hydrogen, carbon, nitrogen, oxygen, phosphorous, and sulfur atoms, which scatter weakly. In order to enhance the diffraction signal, therefore, it is necessary to increase the intensity of the incident beam as well as the scattering volume of the sample. This is achieved by shining highly focused, collimated X-radiation onto crystalline samples, that is, well-ordered, symmetrical, three-dimensional arrays. These preliminary studies led to further investigation of the diffraction properties of pepsin crystals by J. D. Bernal and D. Crowfoot from the Cavendish Laboratories at Cambridge, during the mid-1930s. They recognized that biomacromolecular samples must be kept in an aqueous, more native-like environment ("mother liquor") rather than as dry-mounted crystals.

2. The first breakthroughs: hemoglobin and myoglobin (1940–1970)

In 1937, Max Perutz performed the first experiments to find out whether it might be possible to determine the atomic structure of hemoglobin by X-ray diffraction. It took Perutz until 1953 to achieve the most critical breakthrough in actually visualizing such complex structures. He succeeded in incorporating heavy atoms, namely, those of mercury, into definite positions in the hemoglobin molecule. The diffraction pattern, in this method, is altered to some extent and the changes are utilized to determine a direct image of the hemoglobin molecule, within three-dimensional crystals. This method provided for the first time a solution for an often-insurmountable problem in X-ray structure determination, known as the *phase problem*.

Using the same technique, which became known as Multiple Isomorphous Replacement (MIR), Kendrew succeeded in incorporating heavy atoms (mercury and gold) into myoglobin crystals. By 1958, the structures of myoglobin and hemoglobin had been determined after more than 20 years of dedicated labor, and for these groundbreaking discoveries, Perutz and Kendrew were awarded the Nobel Prize in Chemistry in 1962. Within the next 5 years, the first structures of the enzymes lysozyme, carboxypeptidase, RNase S, chymotrypsin, subtilisin, and papain were also determined at near-atomic resolution.

3. Recent history (1970–1990)

In the 1970s and 1980s, X-ray crystallography continued to flourish. This was due to further development of the theoretical background and dramatic improvements in experimental designs and computational methods. In the computational area of research, the technique of "molecular replacement" represented a major breakthrough in overcoming the phase problem. Provided a homologous or sufficiently similar structure is already available, phases could be derived initially from a randomly placed but structurally related model. The model orientation and position relative to the origin would then be corrected (and optimized) by dissecting the molecular replacement procedure into a rotational and translational search. The search procedures are based on principles derived by Patterson, Crowther, Rossmann, and Huber.

In the 1980s and 1990s, computer hardware had advanced so much that it was possible to carry out most of the mathematically challenging work, including structure refinement and graphics computer-based model building. This period saw the introduction of highly interactive graphics programs such as FRODO and O by T. A. Jones, or refinement routines such as PROLSQ by J. H. Konnert and W. A. Hendrickson, TNT by D. E. Tronrud and XPLOR by A. T. Bruenger. The latter routines employed fast Fourier transforms (FFT) and least squares (LSQ) methods for structural refinement. Major improvements in the efficiency of structure refinement came about with the implementation of molecular dynamics (temperature bath-coupled, simulated annealing) algorithms in CNS. These techniques proved more powerful than least squares methods due to an increase in the radius of convergence. The introduction of the Free R-factor, a reliability index calculated between the refined structure and a set of omitted, thereby, unbiased set of observed X-ray reflections, substantially increased the reliability and accuracy of refinement procedures. The manual (computer-based) intervention in generating and fitting atomic structures in conjunction with a certain degree of automation in the subsequent refinement procedure caused a dramatic increase in the number of structures deposited in the Protein Structure Databank (PDB).

Besides many improvements in computational methods, experimental techniques were advanced as well. Historically, diffraction intensities had been recorded on X-ray sensitive films, followed by amplitude estimation by eye or by digitizing on a rotational scanner. In the 1980s, X-ray-sensitive area detectors with big apertures, however, became available and have since had a major impact on the accuracy and the speed of X-ray data collection. Imaging plate detectors

use polyester plates coated with highly dispersed barium fluorohalide phosphor crystals (BaF(Br,I):Eu2+). The recorded X-ray diffraction intensities are read out through photoactivation with a laser and recorded by a photomultiplier. A further improvement in data acquisition speed and accuracy came about with the implementation of charge coupled device detectors (CCD) in the early 1990s. CCD detectors allow the direct readout of a current that is generated by an incident photon onto an X-ray-sensitive phosphor that is backed by arrays (up to 4096 × 4096 pixels) of tiny, siliconoxide-based capacitors coupled to tapered optical fibers. The pixels have a diameter of about 10 µm, and by using paneled CCD designs (2 × 2 or 3 × 3 arrays), the apertures are sufficient for macromolecular X-ray data collection. The readout time (or "dead-time") of such a device is less then 1 s, thereby substantially decreasing collection time to hundreds of minutes rather than days.

Synchrotron rings have had and will continue to have a major impact on the analysis of macromolecular structure. The charged particles within the storage ring generate electromagnetic radiation when diverted from a straight path, through a magnetic field generated by a bending magnet. Insertion devices, such as multipole wiggler magnets or undulators, further modify the path of the electrons (or positrons) and allow modification of the X-ray wavelength. The wavelength can be selected not only to reduce radiation damage but can also be tuned to meet specific scattering properties of the biological sample or bound ligands. This has been particularly successful in utilizing anomalous diffraction characteristics (or X-ray fluorescence) of heavier chemical elements such as Se, Fe, Zn, Cu, and so on. Single or multiplewavelength anomalous dispersion (SAD/MAD, pioneered by Wayne Hendrickson) and single isomorphous replacement in conjunction with anomalous scattering (SIRAS) have now become the phasing method of choice. These phasing methods are based on the anomalous effect, which in turn is a wavelength-dependent phenomenon. Anomalous scattering usually occurs in heavy atoms such as sulphur, bromine, iodine, and, prominently, in main and transition group metals. The effect is caused by the interaction of X-ray photons with outer shell electrons in the anomalous scatterer. Some photons may be absorbed and reemitted at lower energy ("fluorescence"), but more importantly, some photons are absorbed in a wavelength-dependent manner and immediately reemitted at the same energy. Such scattered photons gain an additional imaginary component to its phase, indicating that it is being retarded compared to a normally scattered photon. Accordingly, the atomic form factors of heavy atoms should be separated into the following components:

$$f_{\text{tot}} = f_{\text{norm}}(\theta) + f_{\text{anom}}(\lambda) = f_{\text{norm}}(\theta) + f'_{\text{anom}}(\lambda) + i f'_{\text{anom}}(\lambda) \quad (1)$$

The differences in intensities (Bijvoet differences) and in phase shifts (retardation) can be utilized to overcome the phase problem. The differences in anomalous amplitudes are usually considerably smaller than those obtained from MIR and require a high degree of accuracy in measuring individual intensities by using more intense X-ray beams and highly sensitive detectors.

4. Present and future (2000–2010)

Recent advances in computational approaches using Bayesian statistics and maximum likelihood methods have helped to facilitate initial phase determination and have proved very useful in overcoming problems in phase refinement. Maximum likelihood methods as implemented in the programs CNS and REFMAC have also been applied to X-ray structure refinement. Automated Patterson search procedures in conjunction with partially or fully automated fragment-based model building and structure refinement routines have helped a great deal in simplifying and speeding up the entire process of structure determination and refinement.

Structural proteomics programs brought about major technical advances in high-throughput methods such as the use of robotics in crystal growth, screening, mounting, X-ray data collection, and evaluation. The brilliance of modern synchrotron beams combined with very short exposure times have dramatically increased the speed of structure determination. The future of single crystals diffraction methods lies in the development of even more powerful, tunable radiation sources such as the X-ray free electron laser (XFEL). Single exposure times will decrease well below the second scale, opening up opportunities for time-resolved diffraction studies, an area that has shown a lot of promise by using polychromatic X-radiation but has been hampered by inherent technical difficulties with Laue diffraction.

To this day, however, diffraction methods remain the most commonly used, successfully applied, and productive techniques to elucidate macromolecular structure. In 2004, the Protein Data Bank (**www.rcsb.org**) lists more than 28 000 entries with approximately 85% of the deposited structures determined by single crystal diffraction. Major advances in multidimensional NMR techniques are contributing significantly to our understanding of macromolecular structure, particularly with respect to their dynamic properties. With the recent advances in cryogenic techniques at liquid helium temperatures, electron diffraction and cryogenic imaging techniques have begun to make major contributions to structural studies at the molecular level. Combination of these techniques along with correlating structure, function, and dynamics provides a more complete understanding of biomacromolecular structure.

Specialist Review

Fundamentals of protein structure and function

James R. Bradford, Jennifer A. Siepen and David R. Westhead
University of Leeds, Leeds, UK

1. Introduction

The amino acid sequence of a protein encodes its three-dimensional (3D) structure, which in turn determines its biological function. Proteins have evolved over millions of years to produce a diverse set of structures and can be described as globular, fibrous, or transmembrane. Globular proteins are generally soluble in water, adopt globular 3D shapes, and carry out functions that range from enzyme catalysis to transport and storage. Fibrous proteins usually perform a structural role, with examples including collagen, α-keratin, and elastin. Integral transmembrane proteins exist in lipid membranes and their functions include forming channels through which molecules or ions can pass, and participating in signal transduction by conveying chemical messages into and out of the cell. Invariably, these functions require that proteins interact with each other or with different molecules such as DNA. Therefore, to understand the relationship between a protein's structure and function fully, knowledge of that protein's evolutionary history and its interactions is essential.

2. Primary structure

2.1. Amino acids

Proteins are composed of 20 "standard" amino acids, which contain an amine group, a carboxylic acid, a hydrogen atom, and a characteristic side chain (R group) all bonded to a central carbon atom, commonly called the alpha carbon (C_α), as shown in Figure 1. Amino acids exist as a zwitterion in physiological pH, with the carboxylic acid deprotonated and the amine group protonated. As a result, they are very soluble in polar solvents such as water but insoluble in most organic solvents. All of the amino acids (with the exception of glycine) are chiral molecules, because they have four chemically distinct groups attached to their chiral center (C_α). Chiral molecules can exist in two different forms (L and D forms), all amino acids that

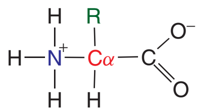

Figure 1 The typical chemical structure of an amino acid. R represents the variable side chain

form natural proteins have the same relative configuration about their C_α atoms and adopt the L form.

Each of the 20 amino acids are characterized by distinctive physicochemical properties that include polarity, acid/base properties, aromatic properties, bulk, conformational flexibility, cross-linking ability, hydrogen-bonding capability, and chemical reactivity. These properties are interrelated and largely responsible for the great range of protein properties. Amino acids are often classified into three groups, hydrophobic, polar, and charged, as shown in Figure 2, on the basis of the chemical nature of their side chains.

2.2. *Peptide bond*

During protein synthesis, amino acids polymerize in a head-to-tail arrangement, extending from the N (amino) terminus to the C (carboxy) terminus, by the formation of peptide bonds between two successive amino acids. A peptide bond is formed between adjacent residues by a condensation reaction (the elimination of water) between the amino group of one residue and the carboxyl group of another (Figure 3). This polymer, which can contain approximately 40 to over 4000 amino acids, is called a *polypeptide*. The main chain or backbone of the polypeptide is composed of the C_α atom, to which the side chain, an NH group and a carbonyl group (C'=O) are attached and a peptide bond joins C' of one residue to N of the next. In the 1950s, Linus Pauling and Robert Corey (1951) observed that peptide groups, with few exceptions, assume the planar trans conformation, in which successive C_α atoms are on opposite sides of the intervening peptide bond.

2.3. *Polypeptide backbone*

The conformation of the polypeptide backbone may be described by two repeating dihedral angles, shown in Figure 4, about the C_α–N bond (phi, ϕ) and the C_α–C bond (psi, ψ), the third repeating angle about the N–C bond (omega, ω) is generally fixed at 180°. Sterically forbidden conformations of the ϕ and ψ angles are those in which the nonbonding interatomic distances are less than the corresponding van der Waals distances. The Ramachandran diagram (Figure 5), so called after its inventor G. N. Ramachandran (1968), shows the allowed ϕ and ψ angles in proteins in which all the common types of regular secondary structure (discussed later) that are found in proteins fall. The conformational angles of most residues in 3D X-ray determined structures (*see* Article 104, **X-ray crystallography**, Volume 6) are observed to lie in the allowed regions of the Ramachandran diagram. The only exception is glycine: possessing only a hydrogen atom as its side chain confers

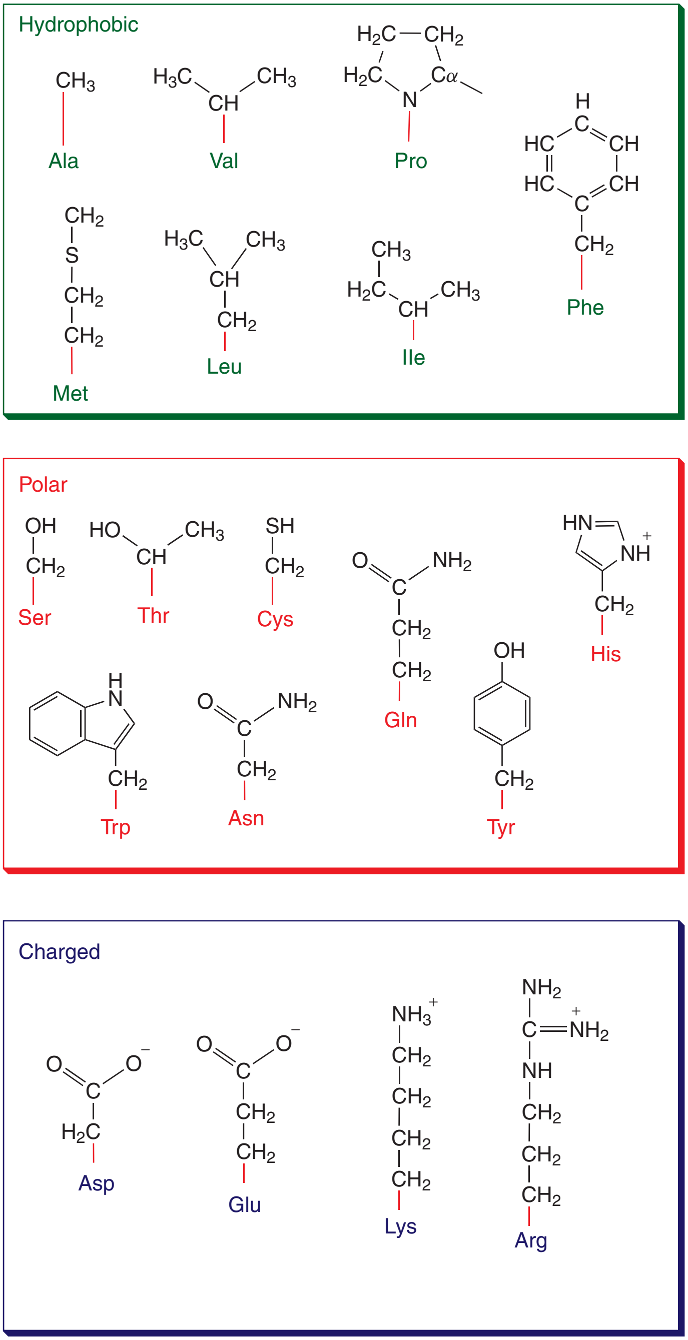

Figure 2 The chemical structures of the 20 amino acids

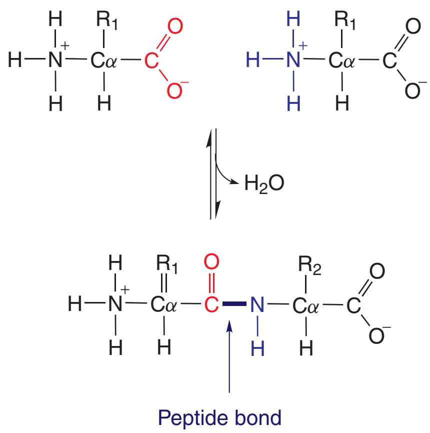

Figure 3 The formation of a peptide bond

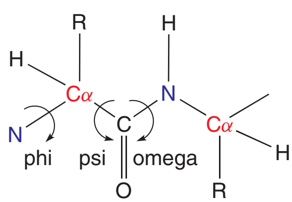

Figure 4 Backbone torsion angles

to it greater than normal flexibility on the polypeptide chain by reducing steric hindrance.

3. Secondary structure

Polypeptide chains form hydrogen bonds between the N–H and C′=O of different residues to form regular secondary structure elements, where consecutive residues have similar ϕ and ψ angles. The two most common secondary structure elements are the alpha (α) helix, formed from a stretch of consecutive residues in the polypeptide, and the (β) beta sheet, where hydrogen bonding occurs between different regions of the polypeptide chain.

3.1. α-Helix

Hydrogen bonding between the C′=O group of residue n and the N–H of residue $n + 4$ results in an α-helix with ϕ and ψ angles of approximately -60^{o} and -50^{o} respectively. An α-helix contains 3.6 residues per turn and each turn is 5.4-Å high (the pitch of the helix); they vary in length from 4 to over 40 residues, with the

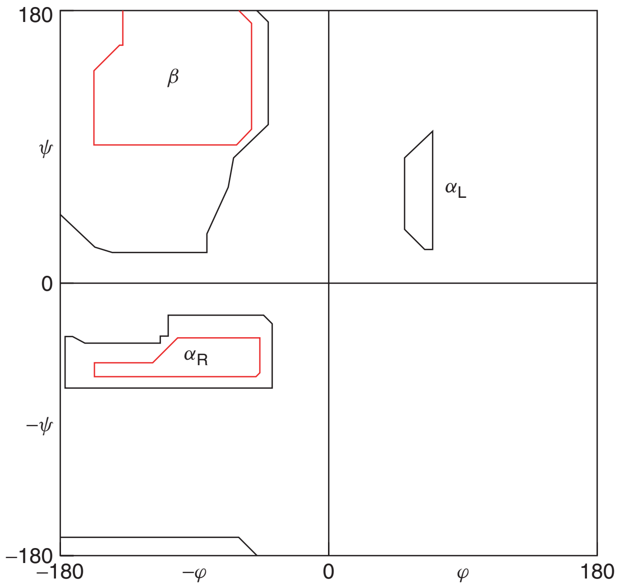

Figure 5 A typical Ramachandran diagram. The red lines enclose the sterically allowed regions for three conformational patterns: right handed α-helices (α_R), left-handed α-helices (α_L) and β-strands (β). The black lines indicate the estimated maximum tolerable limits of steric strain

average helix 10 residues in length (three turns). The α-helix can be right- or left-handed, however, because all amino acids adopt the L form, the alpha helices are nearly always right handed. Other helical structures exist that are either more or less tightly coiled than the α-helix. The 3_{10} helix (C′=O of residue n is hydrogen bonded to the N–H of residue $n + 3$) and the π-helix (C′=O of residue n is hydrogen bonded to the N–H of residue $n + 5$) are less energetically favorable than the α-helix because the packing of the backbone atoms is less stable. They are a rare occurrence in protein structures and are usually present at the end of α-helices or as single turn helices.

3.2. β-Sheet

Continuous stretches of the polypeptide chain, usually 5–10 residues, can form β-strands and these strands hydrogen bond to other β-strands from a different region of the chain. When every adjacent strand is orientated in the same direction, in terms of the N- and C-terminus, a parallel β-sheet is formed, whereas opposing strands form an antiparallel β-sheet. Mixed sheets contain a combination of parallel and antiparallel strands. The hydrogen bonding patterns for the two arrangements are very different and shown in Figure 6. The backbone in a β-sheet is in an almost fully extended conformation, with ϕ and ψ angles of approximately -119^o and 113^o respectively for parallel sheets and -139^o and 135^o respectively for antiparallel β-sheets. The dihedral angles of the β-sheet backbone result in a pleated appearance with a slight right-handed twist. Successive C_α atoms lie a little above and little

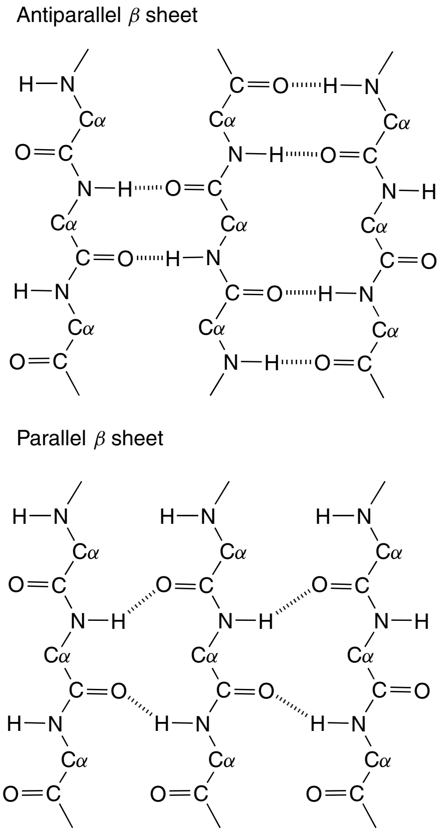

Figure 6 Hydrogen bonding in a parallel and antiparallel β-sheet

below the plane of the sheet and the side chains alternate below and above the sheet.

3.3. Other secondary structures

Proteins structures usually consist of a stable, densely packed core made up of well-defined secondary structure elements. The secondary structure elements are often connected by nonrepetitive elements such as tight turns, β-bulges, and random coil structures. These structures, which are often irregular and varied in length, are usually found exposed to the solvent on the surface of the protein and as a result they are more likely to contain residues that are polar or charged.

Tight turns (also called *hairpin loops* or *reverse turns*) are important aspects of protein structure both structurally and functionally. A tight turn often connects two adjacent antiparallel β-strands and their location on the protein surface suggests their involvement in molecular recognition. There are five types of tight turns depending on the number of atoms forming the turn. The δ-turn is the smallest of the tight turns and involves only two amino acid residues. The γ-turn involves

Table 1 Normalized frequencies of amino acid residues in different secondary structures. Data taken from Levitt M (1978) Conformational preferences of amino acids in globular proteins. *Biochemistry*, 17, 4277–4285

Amino acid	α-helix	β-sheet	Turn	Preferred location

Arg	0.96	0.99	0.88	

three amino acid residues, a β-turn four amino acid residues, the α-turn five amino acid residues and the largest of the tight turns, the π-turn, involves six amino acid residues. A turn that contains more than seven residues is called a *loop*.

There is a strong preference for specific types of amino acids to form specific secondary structure elements. The amino acid preferences for the α-helix and the β-sheet, summarized in Table 1, are an important contributor to early methods of secondary structure prediction from amino acid sequence.

4. Tertiary and quaternary structure

Secondary structure elements and connecting loops combine to form a protein's tertiary structure or fold. This tertiary structure, formed from only a single polypeptide chain, may be sufficient for the protein to carry out its biological function, although in many cases, two or more tertiary structures must come together to attain the protein's biologically relevant oligomeric state. This complex of polypeptide chains is called the quaternary structure of a protein.

Both tertiary and quaternary structures comprise of smaller functional units. A single polypeptide chain can be divided into one or more functional units called domains. Domains may be defined in a variety of ways: as stable structures able to fold and exist independently, as geometrically distinct parts of a 3D structure, as units with a single identifiable function (for example, DNA binding), or simply as

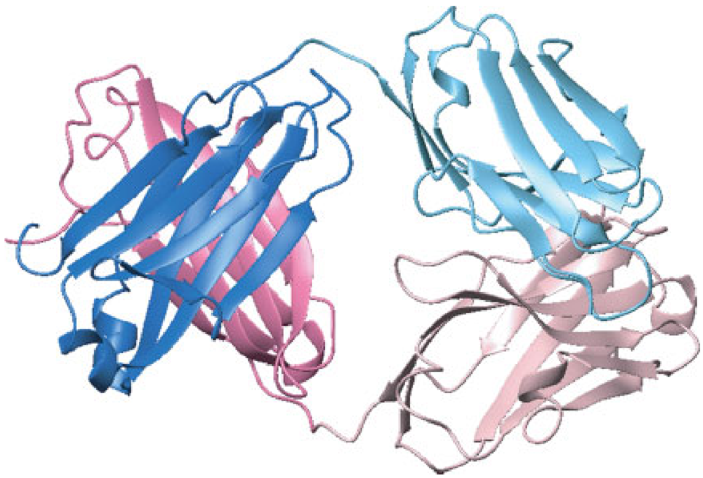

Figure 7 The crystal structure of the monoclonal anti-lysozyme antibody D1.3. The light chain (shown in blue) has two distinct domains, the constant domain (dark blue) and the variable domain (light blue). The heavy chain, shown in pink, also has two distinct domains shown in dark pink (constant domain) and light pink (variable domain). PDB code: 1fld

units observed to occur independently in many otherwise unrelated proteins. The variable and constant domains of the immunoglobulins are illustrated in Figure 7.

In quaternary structure, a polypeptide chain is itself a functional unit called a subunit. Subunits and domains are often equivalent in different species. For example, in mammals a single polypeptide chain of seven domains has evolved to carry out the seven different reactions required for fatty acid synthesis, whereas the same process requires seven different protein subunits in plants (*see* Article 41, **Investigating protein–protein interactions in multisubunit proteins: the case of eukaryotic RNA polymerases**, Volume 5). Indeed, this observation has been used by some as a means to predict protein–protein interactions (*see* Article 45, **Computational methods for the prediction of protein interaction partners**, Volume 5).

Folding of globular proteins is primarily driven by the "hydrophobic effect", where hydrophobic residues aggregate at the core of the protein away from water and polar residues form the solvent accessible surface. Stability of a fold is also achieved by balancing all the other opposing forces that occur between different parts of the protein structure. Attractive electrostatic (also called *ionic bond*, *salt linkage*, *salt bridge,* or *ion pair*) forces exist between two protein groups of opposite charge. There are three main types of electrostatic force: charge–charge (between oppositely charged R-groups), charge–dipole (e.g., interaction of ionized R-groups with the dipole of the water molecule), and dipole–dipole (noncovalent associations between electrically neutral molecules such as van der Waals forces). Hydrogen bonds are extremely important forces in protein structures; they are a permanent electrostatic interaction between a weakly acidic donor group (hydrogen atom with a partial positive charge) and an acceptor atom that bears a lone pair of electrons (negatively charged). In biological systems, both the donor and acceptor can be

highly electronegative, such as nitrogen and oxygen atoms and occasionally sulfur. Van der Waals forces are nonspecific and arise when any two atoms are 3 to 4 Å apart. Although they are weaker and less specific than hydrogen and electrostatic bonds, they become significant when numerous atoms in one of a pair of molecules come close to many atoms of the other. Attractive van der Waals forces are a result of induced dipoles that arise from fluctuations in the charge densities occurring between adjacent uncharged nonbonded atoms. Finally, disulfide bonds are covalent interactions between two cysteine residues, they are frequently found in extracellular proteins where they stabilize the protein against the hostility of the environment such as fluctuating pH and/or temperature.

Integral transmembrane proteins are characterized by predominantly hydrophobic segments that span lipid membranes connected by hydrophilic loops found outside the membrane; thus, forces that control their folding are different to those experienced by globular proteins. Most membrane-spanning segments such as those of G-protein-coupled receptors and the voltage-gated potassium channel are α-helical, while others such as porins form β-barrels. However, examples of X-ray structures of integral transmembrane proteins are rare because their lipid solubility makes them difficult to crystallize.

5. Relationship of sequence to structure

In general, proteins with similar sequences adopt similar structures. Sander and Schneider (1991) used a database of proteins in their normal biologically active confirmations to derive an equation to calculate the percentage sequence identity threshold above which most structures are similar. This equation was subsequently updated by Rost (1999) using more recent data and is shown below:

$$t(L) = 480L^{-0.32(1+e^{-L/1000})} \qquad (1)$$

where L is the length of the alignment and t is the percentage identity threshold. Equation (1) tells us that two protein sequences are likely to share the same basic 3D structure if more than 32% of residues are identical over an alignment length of 80 residues or more. Below this threshold, and certainly below 25%, sequence analysis will not always reveal evolutionary relationships between two proteins. Indeed, many borderline cases exist between 20 and 30% sequence identity; a region described as the "twilight zone" by Doolittle (1986). There have even been examples where two proteins of sequence identity less than 10% are related. Thus, structural comparisons are better than sequence alignments in detecting distant evolutionary relationships between proteins.

These results only apply to naturally occurring proteins of known structure. Some artificially engineered proteins have been proved to have different structures with sequence similarity of as much as 50%. Also, in processes such as amyloid aggregation, proteins can adopt various conformations, following the rules of thermodynamics, under different conditions of temperature, pressure, pH, concentration, or ionic strength.

6. Relationship of structure to function

A protein's 3D structure often reflects the function of that protein. For example, the helix-turn-motif structure of many prokaryotic transcription factors allows them to bind the major groove of DNA. Also, the segments of proteins that span membranes, such as voltage-gated potassium channels, are often α-helical. There are numerous ways of describing the function of a protein. For example, trypsin is a serine endoprotease but can also be described as an enzyme that participates in the degradation of other proteins. A number of attempts have been made to classify protein function but probably the most comprehensive has been the Gene Ontology (GO) scheme (**http://www.geneontology.org**). Ontologies are structured, controlled vocabularies that GO collaborators hope to apply to gene products across different databases and organisms. Three ontologies are being developed to describe gene products in terms of their associated biological processes, cellular components, and molecular functions in a species independent manner. For example, actin takes part in muscle contraction (biological process) by binding to myosin (molecular function) within a muscle fiber (cellular component). The ontologies are nonhierarchical and flexible because the relationship of gene product to each of these three categories is usually one-to-many, and descriptions of a gene product in the literature are often incomplete.

Knowledge of a protein's 3D structure is essential to understanding its function. Indeed, for those proteins whose function has yet to be assigned, there has been considerable effort to infer function from 3D structure alone. The most useful protein structures are complexes, where proteins are observed in interaction with other proteins, nucleic acids or smaller molecules, because they reveal the location of the key functional areas including the interaction site. Calculating the geometric and physical–chemical properties at these sites helps determine the molecular mechanism of function at the atomic level. Even without a complex structure, useful information can still be sought from an individual protein structure such as which residues are located in the structural core or in contact with solvent.

7. Evolution of structure and function

To understand the relationship between a protein's structure and function fully, consideration of that protein's possible evolutionary history is essential. Proteins evolve through mutations in their genes, sometimes in combination with more dramatic genetic events. The most common type of mutation is a point mutation involving substitution of a single nucleotide. Deletion or insertion of one or more base pairs can also occur. Only mutations that result in neutral or advantageous changes are permitted, so residues playing a critical role in structural stability or function are generally conserved. Exceptions to this rule include the major histocompatibility (MHC) molecules of the immune system, which rely on high mutation rates at their binding site to adapt to foreign proteins. Buried residues

evolve more slowly than residues on the protein surface because the efficient packing of the protein's hydrophobic core must be kept intact. Usually, it is the secondary structural elements such as helices and strands that reside in the hydrophobic core, alternating with loops found predominantly at the surface. Therefore, loops evolve more rapidly than secondary structure elements. The functional response to the effect of mutations at different locations on the protein can often be explained by the changes in structure that the mutations cause.

Point mutations usually lead to only minor improvements in function. More substantial genetic changes such as gene duplication, domain recombination, domain swapping, or migration are less common although they often confer a major and immediate selective advantage on the organism. Gene duplication produces two copies of a protein domain that either evolve separately or fuse to produce a homodimer, which then undergoes mutation and selection. Most gene duplications probably result in the production of a pseudogene that is without function and not expressed, but occasionally a new and advantageous function may emerge. The regulatory protein α-lactalbumin is thought to be the product of duplication of a gene encoding the enzyme lysozyme. Subsequent mutations changed key functional residues but retained the overall structure of the protein, resulting in two homologs carrying out completely different functions.

Two unrelated domains can also combine to enhance a protein's function in a process called domain recombination. Many regulatory domains of enzymes such as the plasma proteases have arisen through a combination of duplication and recombination events. Some monomers have acquired oligomeric properties by domain swapping – the mutual exchange of domains or structural elements between each molecule of a dimer. These structures, including some members of the ribonuclease family, are often in dynamic equilibrium with their monomers, thus providing a mechanism for changing quaternary structure via small changes in sequence. Occasionally, functional residues, especially catalytic residues in enzymes such as the α/β hydrolases, can migrate to different structural elements making function prediction on the basis of homology difficult in these cases.

Proteins are subject to both divergent and convergent evolution. Proteins related by divergent evolution derive from a common ancestor and are called *homologs*. In extreme cases, divergent evolution can operate until sequence similarity between homologs is almost undetectable. For example, members of the globin family, including hemoglobin, myoglobin, and plant leghemoglobin, adopt the same overall structure and carry out oxygen transport by the same mechanism, but often share less than 20% identical residues. This demonstrates that structure evolves much slower than sequence and with the wealth of new structures now available, many evolutionary relationships that could not be identified by sequence have recently been uncovered. Proteins related by convergent evolution derive from different ancestors but arrive at the same structural solution to achieve a particular function. As a result of convergent evolution, both chymotrypsin and bacterial subtilisin share the same Ser-His-Asp catalytic triad and function as serine endopeptidases via the same catalytic mechanism. However, they are completely unrelated at the level of overall tertiary structure.

8. Protein interactions

8.1. Molecular recognition

There are at least three types of protein contact: crystal contacts, contacts between protein subunits, and contacts between two interacting molecules. Crystal contacts are nonspecific and an artifact of the crystallographic process used to elucidate protein structure; they are not biologically relevant and will not be dealt with here. Contacts between protein subunits provide the basis for quaternary structure as we have seen. Therefore, for the rest of this chapter, we are concerned with contacts between two interacting molecules, at least one being a protein. All metabolic and regulatory processes such as enzyme catalysis, molecular transport, signaling, the immune response, and gene expression involve protein interactions.

The cell is usually a crowded environment, so a protein has many potential binding partners. All these molecules have a certain specificity and affinity for each other. Specificity is the capacity to select between binding partners, especially those that have similar surface properties, whereas affinity is the capacity to interact with the chosen binding partner. Most proteins, such as enzymes and their inhibitors, have only one or two binding partners (highly specific), although some have multiple binding partners (multispecific). Multispecificity can arise when members of a protein family recognize a specific pattern on the target protein. For example, SH2 and SH3 domains bind to proteins with phosphotyrosine and proline-rich sequences, respectively. Different protein functions require different levels of specificity and affinity, so a tight control of these factors is necessary. Two proteins that have high affinity towards each other may not necessarily have high specificity, as with the interactions involving SH2 and SH3 domains.

When a molecule interacts with another molecule, an interface between the two molecules is formed. This interface is defined as the area of the protein surface that is buried (removed from contact with water) as the interaction takes place. Interfaces between participating molecules must be complementary in both shape and physical chemistry. Protein interactions are therefore driven by molecular recognition. Molecular recognition is defined as the interpretation of all the shape and physical–chemical information required by a molecule to select and interact with its binding partner.

The molecular recognition process begins with a protein and its binding partner completely surrounded by a solvent (usually water) but in close proximity. Proteins interact with their solvent, so some of these interactions must be broken if a complex is to be formed, a process called *desolvation*. Unfortunately, van der Waals, electrostatic, and hydrogen bonds that form between a protein and its binding partner are generally not as favorable as those between protein and water, so the energy barrier desolvation provided is difficult to overcome. As one would expect, desolvating nonpolar parts of the protein surface is easier than desolvating polar and charged areas. Desolvation of nonpolar areas releases water molecules and therefore increases solvent entropy. This hydrophobic effect is a major driving force behind complex formation, just as it is behind protein folding, and partially compensates for the desolvation penalty. The proteins themselves will also be subject to energy changes due to two molecules effectively becoming one.

Translational and rotational entropy will decrease, and there will also be changes in vibrational entropy. Some conformational entropy will also be lost because of the restriction of dihedral angles. The complex conformation usually puts significant strain on the individual proteins involved, which means that their internal energies will be higher in the complex than when apart. Nevertheless, the resulting complex conformation is usually the most energetically favorable that can exist.

8.2. Types of protein interaction

There are three main types of protein interaction: protein–small molecule, protein–DNA, and protein–protein. Small molecules, in this sense, include ATP, GTP, metabolites, and some inhibitors or drugs. Proteins binding DNA include promoters, repressors, and transcription factors; their binding sites are characterized by large, positively charged electrostatic patches on the protein surface, matching the negatively charged DNA phosphate backbone groups. Protein–protein interactions usually involve two or more polypeptides of lengths greater than 20 amino acids. Recently, Nooren and Thornton (2003) have described two ways of classifying protein–protein interactions based on the components and lifetime of the complex. Interactions between identical chains occur in homo-oligomers (Figure 8), whereas those between nonidentical chains occur in hetero-oligomers. Most homo-oligomers are obligate, meaning that their individual components cannot exist as stable structures independently in vivo. By contrast, most hetero-oligomers are nonobligate (Figure 9) in which each component can exist as a stable structure under physiological conditions. Interfaces on obligate complexes are generally large and hydrophobic. Nonobligate complexes exhibit a more polar interface, because

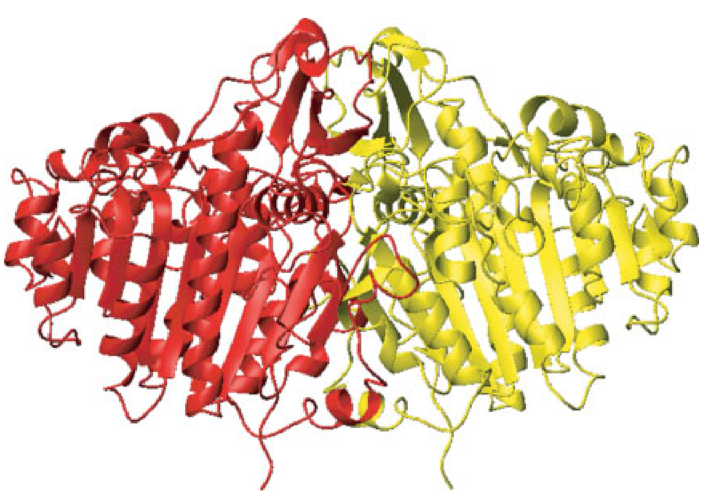

Figure 8 Alkaline phosphatase: an example of a homodimeric, obligate interaction. PDB code: 1b8j

Figure 9 Complex of acetylcholinesterase (red) with its inhibitor fasciculin II (yellow): an example of a heterodimeric, transient interaction. PDB code: 1fss

the monomers have to function independently. A large exposed hydrophobic patch would be unstable, possibly leading to aggregation events.

Interactions can be further classified as permanent, weak transient, or strong transient according to the lifetime of the complex. Permanent interactions are very stable and mostly, but not always, occur in obligate complexes. Weak transient interactions occur between two proteins that need to associate and dissociate continuously in vivo. The local concentration of the protein components, ions and solutes, and changes in pH and temperature all influence weak transient interactions. Strong transient interactions are more stable so require a molecular signal to initiate association or dissociation. For example, guanosine triphosphate (GTP) binding to G proteins causes their dissociation into Gα and G$\beta\gamma$ subunits, but the dephosphorylation of GTP to guanosine diphosphate (GDP) initiates the trimer to reform. A transient interaction may become permanent under certain cellular conditions but usually the type of interaction is inferred by the function of the protein. For instance, intracellular signaling requires rapid association and dissociation so interactions are transient.

The different types of protein interactions, and the diverse range of protein biological functions illustrate that a protein's function and structural properties are intrinsically linked. This tailoring of structure to function has been brought about by evolution over millions of years. A detailed understanding of how this diverse set of structures are assembled from amino acid sequences will provide yet further insights into evolutionary history and function. The articles in the remainder of this

section describe the recent developments and improvements in methodology that will accelerate this process of discovery in the coming years.

1. Introduction

Microbial, viral, animal, and plant genome projects have generated enormous interest and have provided a critical milieu of data into the elucidation of all cellular components, their interactions, and regulation. The Human Genome and other genome sequencing projects have also accelerated the pace of discovery in biology and medicine. In the past several years, accumulation of sequence data has increased significantly. 1421 genome projects are currently underway (**http://www.genomesonline.org/**). The sequences of 263 genomes have been completed, annotated, and made available to the public. The phylogenetic diversity of the genomes that have been sequenced is increasing. Sequencing of 489 eukaryotic genomes is underway, and the sequence of a diatom genome, a unicellular photosynthetic, and eukaryotic algae was recently published (Armbrust *et al*., 2004). For the first time, the entire set of proteins and RNA coded by the genome have become available for experimental and theoretical studies. Genomic analysis has addressed numerous questions such as a minimal set of genes required for performing essential biochemical functions (Mushegian and Koonin, 1996; Koonin, 2000), the total number of protein families coded by genomes (Pearl *et al*., 2005; Grant *et al*., 2004), and the relationship between protein sequences and biochemical functions (Andrade *et al*., 1999; Todd *et al*., 2001). At the same time, biologists have raised questions about the structural repertoire of proteins coded by genomes and a basic set of proteins folds utilized by living organisms (Wolf *et al*., 2000; Qian *et al*., 2001; Holm and Sander, 1996; O'Toole *et al*., 2003).

In the past 50 years, biologists have focused primarily on the proteome components of a few model organisms. Since 1980, recombinant DNA technology has allowed in-depth investigation of virtually all cellular components, and these capabilities were further expanded by the availability of complete genome sequences. As a result, the most fundamental processes of the living cell are quite well characterized (e.g., translation, most fundamental metabolic pathways, transcription regulation, replication, RNA splicing, chaperone-mediated protein folding) (Harrison, 2004). Some important gaps remain in our knowledge, on average, nearly 50%

of all genes in a typical genome are described as uncharacterized or hypothetical and 10–15% of genes have no sequence relative (ORFans/singletons) (Liu *et al*., 2004; Jordan *et al*., 2001; Jordan *et al*., 2004; Siew and Fischer, 2004).

The complete understanding of the functions of biological systems requires detailed knowledge of proteins and their interactions with other proteins and cellular components. To carry out their functions, including molecular recognition and catalysis, proteins require a correctly folded 3D structure (Erlandsen *et al*., 2000; Dobson, 2003). Therefore, the knowledge of a protein structure is essential. However, a protein structure not only contributes to comprehending underlying chemical principles of protein function but also adds to our understanding of the evolution of biological systems, since the protein sequence does not always allow the prediction of structure and function (Pearl *et al*., 2005; Bray *et al*., 2000).

The multitude and complexity of molecular interactions, and their temporal and transient nature, requires basic information about the structures of individual components as well as of the complete functional assemblies (Saibil, 2000; Halic *et al*., 2004; Dormitzer *et al*., 2004). The individual proteins are very important in their own right as agents of health and disease or as tools with economically significant applications (Eckhardt *et al*., 2004; Zweiger and Scott, 1997). In the last four decades, structural biology, thanks to the generous public and private support of hypothesis driven research, has been quite successful at addressing fundamental mechanistic and functional questions in biology – we understand the most basic principles of protein structure. The 3D structures of many important classes of proteins, including enzymes and receptors, and the structures of at least one member of approximately half of the largest protein superfamilies are available. Structures of several important large protein assemblies are known as well (Ban *et al*., 2000; Abrahams *et al*., 1994; Murakami *et al*., 2002; Simpson *et al*., 2000; Schlunzen *et al*., 2001).

Although many proteome components of the fundamental processes of the living cell have been characterized structurally, the number of specific structures from individual species is very low, except for a very few cases such as *Escherichia coli*. Homology modeling coverage is higher, and can reach 40–50% of all proteins (Goldsmith-Fischman and Honig, 2003; Zhang and Skolnick, 2004; Eswar *et al*., 2003); however, the models need better accuracy to be applicable for broad biotechnology and biomedical applications. One of the major challenges in structural biology is, therefore, to determine structures of novel proteins encoded by genomes and to increase structural coverage of proteomes in a rapid and cost-effective manner. The vast sequence data provided by genomes made clear that "traditional" structural biology approaches were insufficient to address such a large-scale problem, and at the current pace it would take 40–50 years to complete such a project.

2. Early structural genomics efforts

In the late 1990s, a number of structural biology and bioinformatics groups in North America, Europe, and Asia, stimulated by the rapid progress of genome programs, have initiated small pilot projects. These efforts have tested the idea of using predicted protein sequences from genomes to provide a strategy to

determine structures of all, or at least most, of the structures of proteins encoded by genomes. The important point for the North American efforts was the Argonne's 1998 Structural Genomics meeting (Shapiro and Lima, 1998; Gaasterland, 1998). This meeting brought together researchers and representatives of funding agencies who thought that improvements in technology, combined with the successes of the genome sequencing projects, had set the stage for a large-scale structure determination project. The overall strategy for covering protein structures space was discussed.

X-ray crystallography of macromolecules, in particular, has seen remarkable progress in recent years. These advances were made possible by the public investment in the development of third-generation synchrotron sources (Cassman and Norvell, 1999), initially in European Union, United States, and Japan, and later in other countries, and dedicated beamlines receiving X rays from insertion devices and equipped with modern X-ray detectors (Phillips *et al*., 2002; Westbrook and Naday, 1997). A recent survey of the Protein Data Bank (PDB) (Westbrook *et al*., 2003) showed that contribution of X-ray structures obtained using synchrotrons to the PDB increased from 19% in 1995 to 75.9% in 2004 (Figure 1) (Jiang and Sweet, 2004). The analysis also confirmed that synchrotron sources extend the size of macromolecules for which structures can be solved with equal or better quality, than for other X-ray sources. Moreover, synchrotron facilities accelerated data collection (Jiang and Sweet, 2004; Walsh *et al*., 1999a,b; Hendrickson, 2000), lowered the dependence on large crystals for high-quality data (Jiang and Sweet, 2004), and facilitated new approaches in structure determination (Hendrickson, 1991; Moffat and Ren, 1997; Terwilliger, 1994). The third-generation synchrotron sources also brought a new dimension to protein crystallography by allowing very efficient execution of the structure determination methods that utilize a so-called anomalous signal (multiwavelength (MAD) and single-wavelength (SAD) anomalous diffraction). The PDB survey showed that in 1997 only 12% of all experimentally determined structures were phased using the SAD/MAD approach; this number exceeded 70% in 2003 and 2004 (Figure 2).

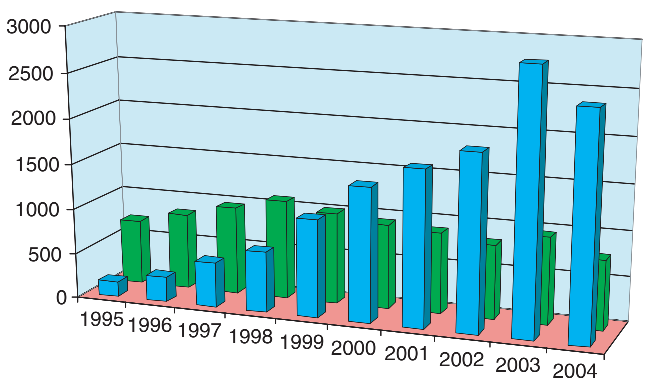

Figure 1 Contribution of structures from synchrotron (blue) and "home" (green) sources to PDB (Jiang and Sweet, 2004)

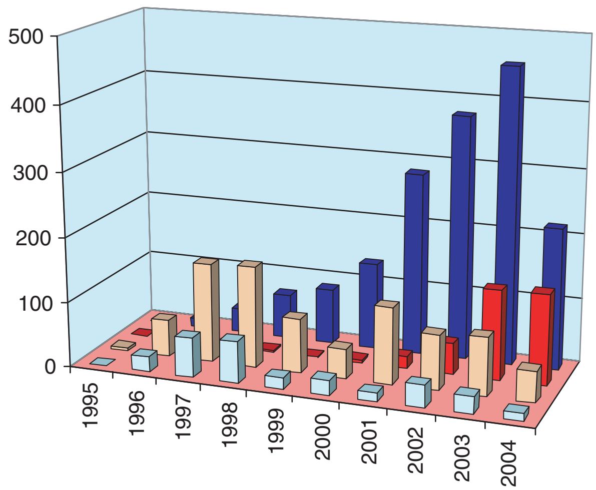

Figure 2 Experimental determination of structures using traditional methods (SIR (light blue), MIR (pale)), and methods utilizing anomalous signal (SAD (red) and MAD (blue)) (Jiang and Sweet, 2004)

The advances in the hardware at synchrotrons could not have been exploited fully if it were not for complementary advances in the software for crystallographic data collection (Otwinowski and Minor, 1997; Terwilliger, 2002; Terwilliger and Berendzen, 1999; Terwilliger, 2004a; Holton and Alber 2004; Brunzelle *et al*., 2003), structure determination and refinement (Terwilliger, 2004a; Brunzelle *et al*., 2003; Bricogne *et al*., 2003; Morris *et al*., 2003; Potterton *et al*., 2002; Adams *et al*., 2002), and high-capacity computing and data storage resources (Brooksbank *et al*., 2005; Ackerman *et al*., 2001; Westbrook *et al*., 2003; Hallin and Ussery, 2004; Manjasetty *et al*., 2003). In fact, many of these developments were driven by the advances in Structural Genomics pilot projects (Norvell and Machalek, 2000; O'Toole *et al*., 2004; Chance *et al*., 2004) and development of synchrotron facilities.

Similar progress has been made in recent years in the field of NMR that continues to be an important contributor to the structural biology with the development of new powerful high-field spectrometers (Montelione *et al*., 2000). NMR is also being applied to difficult proteins such as large soluble and small integral membrane proteins (Kyogoku *et al*., 2003; De Angelis *et al*., 2004). In this review, I will specifically focus on the structural genomics applications in synchrotron-based X-ray crystallography.

In addition to genome sequencing, X-ray crystallography, and NMR developments, there were several major technology breakthroughs that were important for undertaking a major Structural Genomics project:

- well-established PCR-based recombinant DNA technology,
- robust high-level protein expression systems in vivo and in vitro,
- robotic systems for molecular biology,
- robotic systems for protein purification, crystallization, and crystal imaging,

- crystallization formulations for efficient screening protein crystallization conditions and application of crystal cryofreezing to data collection,
- bioinformatics tools, databases, and DNA sequence comparison capabilities.

These developments provided a robust foundation for a large-scale Structural Genomics initiative (Chance *et al*., 2004; Terwilliger, 2000) and allowed for the creation of an integrated structure determination process or a "pipeline" from gene to structure.

3. Emergence of international structural genomics initiative

A Structural Genomics initiative has emerged as a multidisciplinary and international effort to maximize the information value from delineation of the genome content of humans and other organisms (Terwilliger, 2000; Burley, 2000). The initial Structural Genomics goals were: (1) to expand the universe of protein folds by rapidly determining novel structures, (2) to produce homology-based 3D models of all proteins, to extend the coverage of sequence space, and (3) to elucidate novel biological function directly from 3D structure. The ultimate goal was to make it feasible to predict an accurate 3D protein structure on the basis of sequence alone. This will allow inference of variations in functional and 3D structural properties of proteins that result from genetic differences. Additionally, genomic analysis would provide insight into distinctive metabolic capabilities or deficiencies related to the functional capabilities of particular organisms. Development of methods to rapidly scan genetic sequences for potential biological function would impact many fields including health, biotechnology, agriculture, and bioremediation.

The scale of Structural Genomics goals is enormous, clearly comparable with the accomplishments of the past 40 years of structural biology. Maximizing the output of the structure determination pipeline and minimizing the use of valuable resources is a primary requirement for achieving all Structural Genomics goals. At the beginning of this initiative, there were less then 2500 nonredundant structures in PDB (Westbrook *et al*., 2003), and the bioinformatics analysis of available genomic sequences predicted the need to determine 15 000–20 000 unique protein structures (Vitkup *et al*., 2001; Liu and Rost, 2002; Chandonia and Brenner, 2005). This number equaled the scale of all deposits in the PDB. The international structural genomics efforts were initiated, in part, to achieve a more rapid understanding of sequence/structure relationships than would have been accomplished in a problem-focused approach. Several pilot centers have been established to test and improve existing and develop new technologies (Table 1).

The initial Structural Genomics pilot projects focused their effort on developing and establishing working, high-throughput protein structure determination pipelines (Figure 3) (Chance *et al*., 2002; Lesley *et al*., 2002; O'Toole *et al*., 2004). These pipelines include the following important components:

- Genome sequence analysis, family classification, and target selection.
- Efficient production of expression clones, proteins, and crystals suitable for structure determination.

- Rapid protein structure determination using synchrotron-based X-ray crystallography or NMR.
- Advanced robotic and computational systems for semiautomated, rapid data collection, processing, phasing, modeling, and refinement.
- Dissemination to public domain of Structural Genomics results and computational tools for structural, evolutionary, functional, and biomedical analyses. Important requirement included immediate deposition and release of protein structure coordinates.
- Creation of dedicated databases (**http://targetdb.pdb.org/**) (Chen *et al*., 2004) and dissemination of data, materials, and results and training in new technologies.

Initially, different strategies were pursued by various Structural Genomics consortia to determine the most effective experimental strategy (Norvell and Machalek, 2000). Identification of key bottlenecks has been a major effort in Structural Genomics, and this subject was a theme of numerous workshops and conferences (**http://www.nigms.nih.gov/psi/**). Improving selection of targets, better expression of soluble proteins, growth of X-ray quality crystals, automation of X-ray crystallography and NMR structure determination process, and automation and robotics as well as data management have been identified as key bottlenecks.

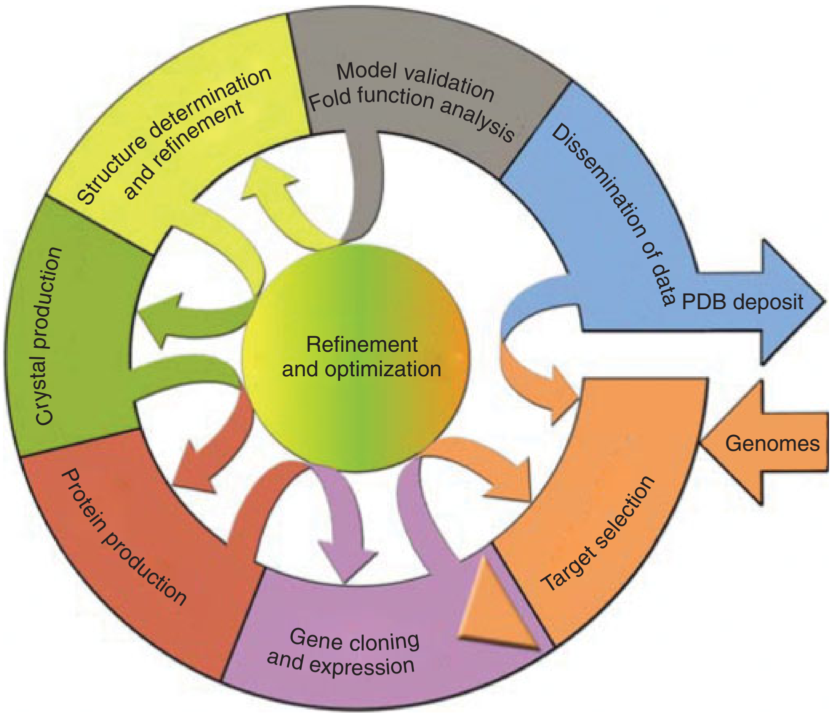

Figure 3 Schematics of the SG structure determination pipeline

At the same time, the Structural Genomics efforts coincided with the information explosion, and this benefited the initiative enormously. It allowed for rigorous and thorough correlative scrutiny of expanding primary and tertiary structural databases for functional significance, and to elucidate novel biological functions by comparison of structural information and genetic sequence databases.

To coordinate the international efforts, the international task forces have been organized to address issues ranging from informatics, target overlap, intellectual property, to data release criteria and their implementation (**www.isgo.org**). Table 1 lists the currently active Structural Genomics programs worldwide.

4. Creation of structural genomics pipelines

Some Structural Genomics pilot consortia have divided the structure determination pipeline into several distinct steps that helped to design integrated systems (Chance *et al*., 2004; Chance *et al*., 2002; Lesley *et al*., 2002). These steps are briefly described below.

4.1. Target selection

Target selection is one of the most important element of Structural Genomics programs (Liu *et al*., 2004; Canaves *et al*., 2004; Watson *et al*., 2003; Bray *et al*.,

2004; Frishman, 2005). Comparative sequence analysis allows the organization of all sequences into families (Chandonia and Brenner, 2005). This is essential for the rational selection of targets and to reduce the number of structures that need to be determined. The structural biologists can select the most suitable family representatives for structure analysis, and select families with particular features (Canaves *et al*., 2004; Frishman, 2005; Kimber *et al*., 2003; Savchenko *et al*., 2003). Since it is not possible to crystallize all proteins, the analysis of protein sequences, to the extent it is possible, is needed to filter protein sequences that are known to crystallize poorly (proteins with internal transmembrane regions, highly disordered proteins, large proteins with domain repeats, etc.). Majority of current Structural Genomics programs focus on soluble proteins or domains of large proteins and use 30% sequence identity cutoff, over the whole protein sequence, with a protein of a known structure as a major selection criterion.

There are a number of other important issues in the target selection strategy. The size of the family to which the protein belongs is important (Watson *et al*., 2003). Large families are preferred over those with few members, since these ensure that many more proteins can be modeled once a template structure is obtained. However, solving the structures of ORFans/singletons, proteins found in a single organism that lack detectable homology to any other protein may be valuable for future structure prediction.

The species distribution of a protein family is also considered in target prioritization (Galperin and Koonin, 2004). Families whose members span phylogenetically distant lineages in all three kingdoms of life are of high interest since they may have an unknown but fundamental function that the solved structure might help define.

Defining the level of detail, or granularity of the structural coverage is an important issue for target selection. Some families may be covered at course granularity, for others more structures and fine granularity coverage would be needed (>=30% sequence identity) in order to produce more accurate models for studying the biological function (Vitkup *et al*., 2001; Chandonia and Brenner, 2005).

Human targets are also important since these structures may have significant biomedical implications.

Various approaches that are used for the prediction of distant evolutionary relationships between all remaining sequences and proteins in the PDB are important. Evolutionary trace analysis is a powerful method for identifying which residues are functionally important and can aid target selection (Yao *et al*., 2003; Joachimiak and Cohen, 2002). Since tertiary structure is better conserved than sequence, structure determination often reveals very distant evolutionary relationships that may yield valuable functional insights.

At the end of the process, a prioritized target list is produced and forms the basis for the experimental work. Analysis of the Structural Genomics success and failure data may help further prioritize certain targets if their sequence suggest they might be more amenable to structure determination – for example, they are more likely to be soluble and crystallize (Canaves *et al*., 2004; Kimber *et al*., 2003).

At present, this analysis is essential but in the future the Structural Genomics plans ultimately to address all protein targets. Currently, there are some protein classes that may not be fully compatible with the Structural Genomics pipelines,

primarily because they are unlikely to be expressed in folded and soluble form in bacterial expression systems.

4.2. Gene cloning and protein expression

To meet the Structural Genomics production levels, a comprehensive 96-well-plate high-throughput technology must be used to generate clones using PCR technology and express soluble proteins (Lesley *et al*., 2002; Dieckman *et al*., 2002). Selected target genes are passed through the automated generation of protein expression clones using liquid handlers and robotic systems. The process consists of a series of interlinked protocols representing liquid manipulations and incubations on various stations of the robotic systems. Ligation-independent cloning protocols have been implemented that simplified sample manipulations and reduced the number of steps (Stols *et al*., 2002; Moy *et al*., 2004). These automated methods provide the capability for high-throughput production of expression clones for Structural Genomics. For the majority of Structural Genomics targets, the proteins are produced at a high level using an inexpensive fermentation process in *E. coli* strains. Considerable effort has also been put into developing a more robust cell-free expression systems (Kigawa *et al*., 2004; Sawasaki *et al*., 2002; Folkers *et al*., 2004).

4.3. Protein production

A critical issue in Structural Genomics, and in structural biology in general, is the availability of many high-quality samples. "Structural-Biology-Grade" proteins must be generated in a quantity and quality suitable for structure determination experiments using X-ray crystallography or NMR. The protein must meet strict quality and quantity criteria. Typically, protein purity of >95% is required. Protein samples must be suitable for incorporation of heavy atoms or isotopic enrichment to aid structure determination. These criteria put certain restrictions on the methods and procedures of sample preparation. A number of Structural Genomics consortia have implemented automated protocols on robotic workstations capable of performing multidimensional chromatography (Chance *et al*., 2004; Lesley *et al*., 2002; Kim *et al*., 2004; Firbank, 2005).

For example, the Midwest Center for Structural Genomics (MCSG) (**www.mcsg.anl.gov**) has developed protein purification procedures that are based on the following principles (Kim *et al*., 2004):

- All proteins are expressed as a fusion with a uniform, cleavable affinity tag.
- Proteins are purified using affinity chromatography followed by buffer-exchange chromatography.
- The affinity tag is cleaved off by a specific tagged protease.
- The protein is further purified using affinity chromatography followed by buffer-exchange chromatography, compatible with protein concentration and crystallization methods.

These protocols can be executed on robotic purification workstations as shown in Figure 4.

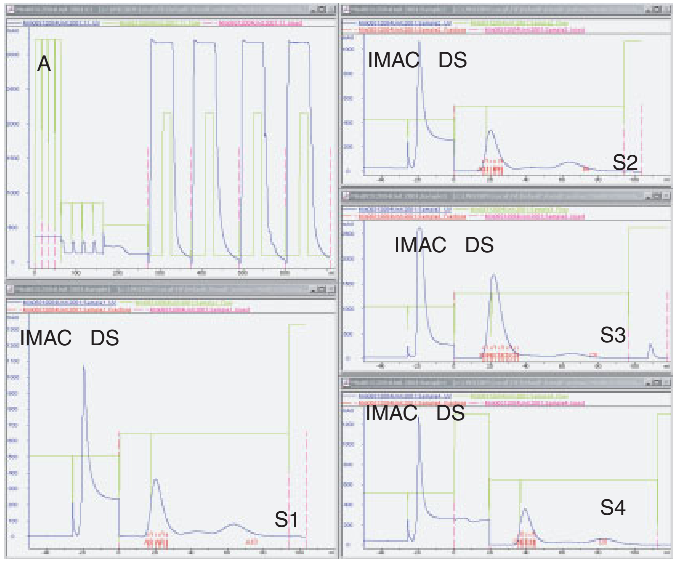

Figure 4 Example chromatograms of IMAC-I and buffer-exchange steps using AKTAexpress from the results file of a four-protein run (APC26434, APC26429, APC26423, APC1976). Load four samples on IMAC and column wash with buffer containing 50 mM HEPES pH 8.0, 500 mM NaCl, 10 mM imidazole 10 mM β-ME and 5% glycerol. (S1, S2, S3, and S4) Wash samples with buffer containing 20-mM imidazole and elution of His_6-tagged target proteins with buffer containing 250-mM imidazole followed by desalting step. In each chromatogram, UV absorbance at 280 nm is plotted versus milliliters of buffer solution flow

Table 2 Protein characterization methods used in SG

Protein parameter	Method of characterization
Purity	SDS-PAGE stained with Coomassie Brilliant Blue and lab-on-the-chip bioanalyzer
Concentration	Protein assay and UV spectrometry
Polydispersity	Dynamic light scattering
Estimated molecular weight in solution	Size-exclusion chromatography, SAXS
Suspected chemical heterogeneity and bound ligands	Mass spectrometry
Bound ligands spectra	UV/Vis spectrometry
Folding, aggregation, homogeneity	HSQC NMR

Purified proteins are typically characterized using a variety of biophysical methods, some of which are listed in Table 2.

4.4. Crystal production

With thousands of proteins and hundreds of different crystallization conditions each, it is essential to use automated crystallization and crystal visualization approaches (DiDonato *et al*., 2004; McPherson, 2004). Typically in the initial trials, proteins are

crystallized using commercially available formulations and crystallization screens. Nanoliter technology has been very successful in rapidly obtaining good quality crystals and at the same time reducing the amount of protein needed for crystallization (Hosfield *et al*., 2003). In an effort to optimize the number of crystallization conditions and maximize their effectiveness, the crystallization data are being analyzed and procedures are adjusted. Recent analysis suggests that large proteins (>60 kDa) and proteins with high pI crystallize less readily using current standard set of crystallization conditions. Such correlations are useful for further optimizing crystallization conditions and aid protein engineering for crystallization (Canaves *et al*., 2004).

Only a fraction of X-ray quality crystals are obtained in the initial crystallization screens. Majority of suitable crystals are produced after more sophisticated optimization of crystallization conditions. In X-ray crystallography, this is one of the major bottlenecks of the structure determination pipeline and is one of the most challenging tasks. A number of strategies have been developed for crystal optimization with the aid of software for experiment design and robotic solution makers and crystallization workstations (Firbank, 2005; Chayen and Saridakis, 2002). Since X-ray diffraction data collection experiments are typically carried out at cryogenic temperatures, crystals must also be cryoprotected prior to conducting the experiments (Pflugrath, 2004; Garman, 2003).

4.5. Structure determination and refinement

For Structural Genomics using X-ray crystallography, the majority of diffraction data are collected at the synchrotron sources, often with an aid of robotic workstations (Hendrickson, 2000; Brunzelle *et al*., 2003; Chance *et al*., 2002; Lesley *et al*., 2002). Typically, a protein with less than 30% sequence identity to a previously deposited structure requires phase-sensitive measurement. Since 2000, so-called anomalous scattering for protein structure determination, either as SAD/MAD, has become the most important means to structure determination and automation (Hendrickson, 2000; Hendrickson, 1991). The success of the SeMet MAD approach (Hendrickson *et al*., 1990), in which methionine is replaced in vivo by SeMet, has made SAD/MAD the most popular technique (Walsh *et al*., 1999a,b). Methionine is found in almost all proteins, and represents 2% of all amino acids. Milligram quantities of proteins in which methionines are quantitatively substituted with SeMet can be routinely produced in vivo (Stols *et al*., 2004; Kim *et al*., 2004) as bacteria, and eukaryotic cells can grow on media containing SeMet (Carfi *et al*., 2002). The substitution can also be accomplished using in vitro expression systems (Yokoyama, 2003). The SAD/MAD method has matured to the point that it has outpaced traditional experimental structure determination approaches as the method of choice for determining the structure of novel proteins (Jiang and Sweet, 2004) (Figures 2 and (5)). Although SAD/MAD relies on a small signal, it has advantages over the MIR method – all data can usually be measured from a single crystal, cryogenically cooled to obtain very accurate phase information. In retrospect, the SAD/MAD techniques currently used by synchrotron facilities truly transformed the field of protein crystallography and Structural Genomics; in fact, SAD/MAD is the key to success of Structural Genomics using X-ray crystallography.

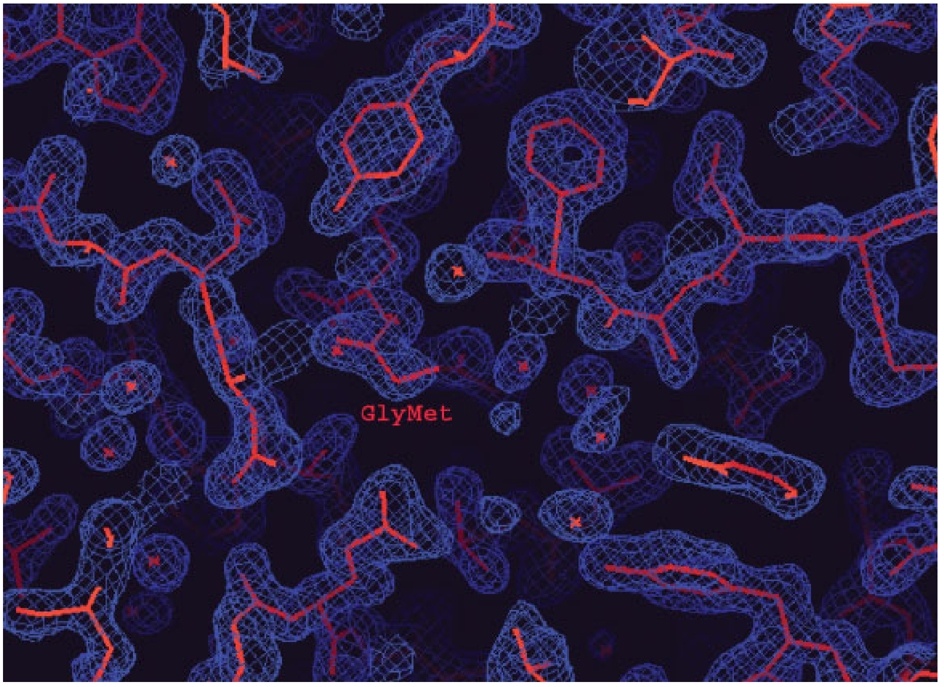

Figure 5 The electron density map for the APC009 protein obtained with 1 Se atom per 297 residues. The phases were obtained from a SAD experiment at the Se-edge. The experimental maps were calculated at 1 s after density modification (Williams *et al*., 2004)

Advances in hardware as well as in data integration and phasing software have resulted in the rapid evolution of experimental protocols. For example, the highly integrated HKL2000_PH suite allows cross talk with other programs and data analysis. This approach is changing protein crystallography from several individual steps linked manually, to a single, multistep, integrated process. The final product, a high-quality electron density map and an initial structural model, is obtained more efficiently (Otwinowski and Minor, 1997).

Some Structural Genomics consortia have developed comparable approaches to structure determination that integrate data collection, reduction, phasing, and model building – significantly accelerating structure determination and reducing the number of data sets required for a single structure determination. These applications convert diffraction data to an interpretable electron density map, and for smaller structures, into an initial model. The initial model is typically an auto-build into electron density maps using a number of excellent software packages (Terwilliger, 2004a,b; Lamzin and Perrakis, 2000; Levitt, 2001). Structures are being refined (Brunger *et al*., 1998; Potterton *et al*., 2002), and final models are still being inspected by experienced crystallographers and are adjusted manually; furthermore, there are efforts to automate these steps as well. Although this article does not address structure determination using NMR, this method and its application to structural genomics is discussed in this volume (Craven, 2005; Kalverda, 2005).

4.6. Model validation and fold/functional analysis

The final protein models are validated using well-established crystallography approaches (Laskowski, 2001; Redfern *et al*., 2005) that are being integrated into pipelines, and structures are deposited to PDB, including structure factors. The protein fold is compared with all proteins that are available in the public databases, and the protein is classified into family and superfamily. There are a number of search tools that can take a protein structure and scan it against the fold databases, and retrieve the closest matches, usually with some measure of the significance of the match (Pearl *et al*., 2005; Redfern *et al*., 2005; Holm and Sander, 1998; Andreeva *et al*., 2004).

One of the important premises of Structural Genomics is that the structure could provide important resources for understanding biochemical function of proteins. A 3D structure provides much more information than a sequence of amino acids. It reveals which residues are on the surface and available for interactions, and which are buried. The surface of a protein, its shape, and electrostatic properties, may reveal binding clefts, charged patches, and conserved regions, potentially involved in function. Clusters of conserved residues may constitute an enzyme's active site, or metal binding site, which may be recognized by comparison with a library of such sites (Redfern *et al*., 2005; Binkowski *et al*., 2003; Sanishvili *et al*., 2003; Kim *et al*., 2003). Crystal contacts may highlight specific interaction patches of biological significance. Structures often include ligands serendipitously revealing cofactors or possible substrates. The structures may also reveal distant evolutionary relationships, which often provide some functional clues, even if the function may have been altered during evolution.

5. Structural genomics contributions (thus far)

Technology development in Structural Genomics programs has been used to increase the efficiency of the protein structure determination pipeline and has also been applied to proteins that pose greater experimental challenges (Heinemann, 2001; Terwilliger, 2004b). Several Structural Genomics consortia have already built pipelines capable of determining over 100 structures per year. Specifically, technological improvements have:

- reduced the time typically needed to solve a new protein structure from months to days;
- reduced the average cost of solving the structure;
- substantially reduced attrition rates at intermediate steps;
- allowed to study new classes of proteins; and
- broadened structural coverage of the protein fold space.

The new technologies, which are now being used in academia and industry, have accelerated new discoveries and have allowed us to comprehensively address large problems in biology. The improvements that occurred during the Structural Genomics pilot stage have also permitted the Structural Genomics pipeline to

accommodate more challenging proteins. For example, the existing pipeline has been used to coexpress interacting proteins for small protein complexes, express membrane-associated proteins without membrane anchors (Zhang *et al*., 2004), express small membrane proteins and soluble domains of membrane proteins (Moy *et al*., 2004), and express domains of large human proteins.

Structural Genomics initiatives are expanding the universe of protein fold space by rapidly determining structures of proteins that were intentionally selected on the basis of low sequence similarity to proteins of known structure. Often, these proteins have no associated biochemical or cellular functions (Watson *et al*., 2003).

The majority of the Structural Genomics programs are now in the fourth year of operation. Thus far, the Structural Genomics efforts have produced nearly a quarter of all novel structures deposited into the PDB. The Structural Genomics pilot projects have already determined 1915 protein structures (vast majority in the past two years). More importantly, over 65% of these structures are unique, based on sequence identity (<30%) as compared with 13% of all deposits to PDB. By the end of 2004, there were totally 26 406 protein structures in PDB, and 4054 (15.4%) were unique. Structural Genomics programs in the past 4 years contributed 1054 or 23.3% of unique structures. More importantly, in some Structural Genomics consortia, the cost per structure has been reduced by nearly 5 times.

Structural Genomics has determined structures of many biomedically important proteins, including many proteins from pathogens. An example is provided in Figure 6, with the structure of sortase B from *B. anthracis* – an important transpeptidase involved in the attachment of proteins to cell surface (Zhang *et al*., 2004). Figure 7 shows structures of 20 DNA- and RNA-binding proteins determined just by one of the Structural Genomics centers in the United States – the MCSG. The scope of this article does not permit more detailed listing of biomedically important structures.

As expected, the determination of many unique structures have lead to the expansion of the protein universe (Hou *et al*., 2003). A number of new folds have revealed proteins with a "knot" (Zarembinski *et al*., 2003; Nureki *et al*., 2004). However, Structural Genomics showed with many examples that proteins with very low sequence similarity have this same fold (and very similar structure). In fact, this confirmed the hypothesis that the structure-based classification of proteins contains far fewer protein families than the sequence–based classification. Clearly, protein structure is better conserved than amino acid sequence, and can reveal distant evolutionary relationships that are undetectable by sequence comparisons. In fact, several structures of ORFans/singletons and proteins from very small families showed familiar folds, contradicting the hypothesis that these families may represent a rich reservoir of new folds (Koonin *et al*., 2002). Structural Genomics data indicate that sequence-based methods have major limitations for identifying proteins with potentially new folds for highly diverged sequences. Structural Genomics results have also raised new questions about the evolution of proteins and protein folds.

Structural Genomics confirmed observation that within a large family of proteins, only truly conserved residues are associated with protein function. In fact, proteins with very different folds and no sequence similarity show virtually identical active

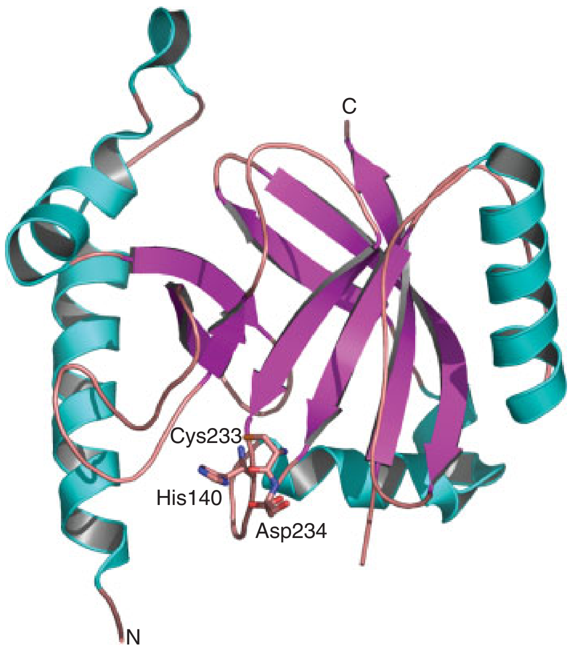

Figure 6 Crystal structure of Sortase B from *B. anthracis*. N- and C-termini and active site residues are labeled (Zhang *et al*., 2004)

sites. Proteins were discovered with different active sites which appear to carry out the same reaction with similar kinetic parameters (Zhang *et al*., 2003a,b).

A number of cofactors have been observed as a part of protein structure and in some cases, we have been able to infer the biochemical and molecular function of the protein directly from the structure (Zhang *et al*., 2002).

The Structural Genomics initiative has already made available numerous profits to structural biology by providing:

- expanded coverage of protein fold space with a dictionary of high-resolution protein structures determined experimentally by synchrotron-based X-ray crystallography and NMR;
- new structures of proteins with medical importance;
- new reagents for broad use;
- a comprehensive library of recombinant protein expression clones representing protein structures and functions;
- new high-throughput technologies for the currently powerful but tedious and labor-intensive protocols of molecular biology, protein expression, purification, crystallization, and structure determination;
- some functional information derived from structure; and
- comprehensive Structural Genomics databases.

As the field of structural genomics matures and accumulates a large volume of data, it will represent nonreductionist cell biology research, making it possible to

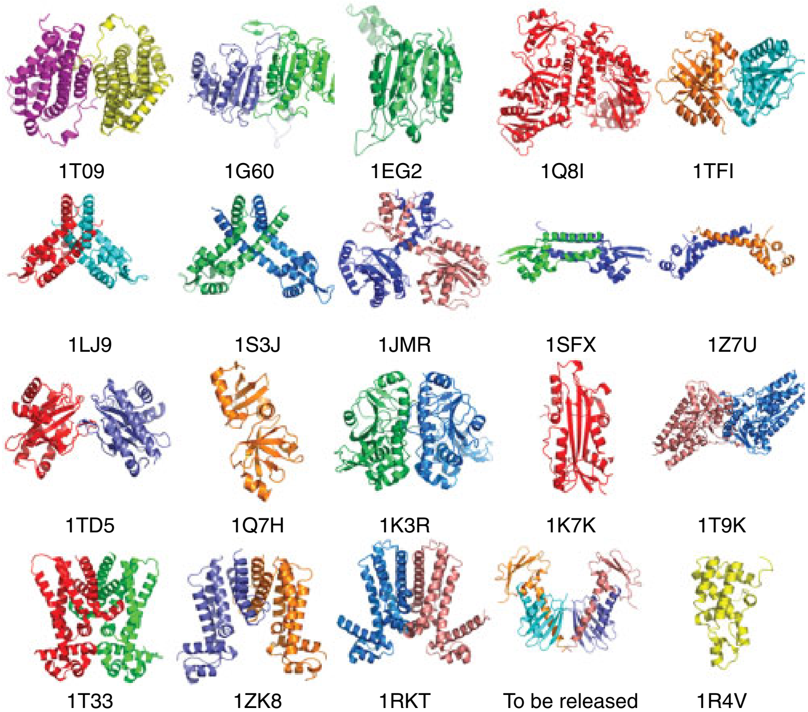

Figure 7 Models of DNA- and RNA-binding proteins determined at the MCSG

develop hypotheses at the integrated cell level. For this to occur, a high degree of completeness in our knowledge about protein sequence, structure, biochemical function, and biochemical relationships will be necessary. Importantly, many of the tools required for future genomics research are already being developed by structural genomics efforts. It is expected, as illustrated by recent progress of the Structural Genomics initiative, that this field will continue to accelerate the process of scientific discovery. There are a number of challenges that need to be addressed in order to fulfill the ultimate goal of Structural Genomics, to provide complete structural coverage of all major protein superfamilies. These challenges include:

- improved target selection to deliver maximum benefit from each solved structure and provide nearly complete coverage of the protein fold space;
- high-throughput pipelines for all protein classes;
- improved protein expression and solubility, especially for eukaryotic and membrane proteins;
- designing new expression systems to improve protein expression, folding, optimization of target and solubility, including eukaryotic proteins;
- new insights into the structure–function relationship using computational tools;
- improvement of knowledge-based sequence-to-structure and structure-to-function predictions;
- evolutionary links that can give clues to unknown structure/function relationship;

- development of new function-recognition techniques;
- improving methods for target selection and analysis, including domain parsing, identification of signal sequences, and prediction of transmembrane and disordered regions;
- improving crystallization of proteins using orthologs, gene shuffling, surface mutagenesis, chemical modification, and reducing heterogeneity caused by partial ligand occupancy, with the aid of genomic database mining;
- automating crystal screening and optimization of data collection using robotics and automation;
- integrated structure determination and refinement;
- automating structure verification, fold, and functional analysis.

6. Conclusion

The Structural Genomics programs have expanded rapidly and accelerated the structure determination process. Structural Genomics will grow from its goal to produce a collection of individual structures to address the more complex structural biological questions. It will take advantage of all relevant biology data to maximize structural output and impact. Ultimately, structural genomics will become a major component of, and contributor to the next structural biology challenge – visualization of the key stages in reconstruction of all major subcellular macromolecular assemblies and the whole cell. Addressing such complex systems will require exceedingly sophisticated high-throughput structural biology approaches.

Acknowledgments

I would like to thank Lindy Keller for help in preparation of this manuscript, Rongguang Zhang, Youngchang Kim, Monika, and Boguslaw Nocek in preparation of figures. This work was supported by National Institutes of Health Grant GM62414 and by the US Department of Energy, Office of Biological and Environmental Research, under contract W-31-109-Eng-38.

Author's note

I dedicate this article to my mentors Paul. B. Sigler and M. Wiewiorowski

Specialist Review

Target selection for structural genomics

Dmitrij Frishman
Technical University of Munich, Wissenschaftszentrum Weihenstephan, Freising, Germany

1. Introduction: why target selection?

The notion of "target selection for structural genomics" emerged in 1998, when structural genomics itself was officially born (Shapiro and Lima, 1998). As the name implies, it involves generating a putative list of proteins, out of a much larger candidate pool that represent high-priority targets for structure determination. In principle, the need for rational target selection is caused by two competing factors: the quickly growing capacity to solve a large number of structures and, at the same time, impossibility of exhaustive structure determination for all sequences existing in nature. The three basic questions to be answered are what proteins to analyze, how many, and why.

Technical and financial realizability of high-throughput structure determination marked the transition of structural biology from conventional, hypothesis-driven experimental work to a discovery-oriented, observational approach. While in-depth laboratory-scale research on a few selected systems of interest rarely needs external help in deciding which structure to do next, large structural genomics consortia operating in a factorylike fashion critically rely on bioinformatics-driven strategies in this regard.

On the other hand, with the currently available experimental capacities and even with the boldest prognosis as to how these capacities will grow in the future, there is little doubt that it will never be possible to obtain three-dimensional structures for all known protein sequences, the count of which stands at 1 400 000 at the time of writing and doubles roughly every 18 months. For this reason, even the biggest structural genomics consortia potentially capable of solving hundreds of structures within several years of grant funding are still confronted with the question: which particular proteins are the most promising and rewarding candidates for answering a particular biological question.

The mission of bioinformatics-driven target selection is to support the major long-term objectives of structural genomics, which are (1) discovering all types of protein folds existing in nature, (2) providing some sort of structural coverage for all known proteins, (3) predicting function for genomic proteins, and (4) enhancing structure determination technology. Each of these goals is so ambitious

that no single structural genomics consortium, or even the entire structural genomics community, can address them exhaustively. Hence, there is no generally applicable "correct" target-selection strategy: each structural genomics consortium develops its own approach, which suits best its specific scientific goals and experimental capacities. Nevertheless, there are several recurrent themes in target selection that are discussed below.

2. Target list

The centerpiece of the target-selection process is the target list that contains the prioritized list of proteins selected for analysis by a given consortium, and also indicates the experimental stages of work a particular protein has undergone so far, from being selected for analysis via cloning, expression, solubilization, and purification to crystallization, X-ray or NMR-spectroscopic analysis, and structure deposition. For example, the target list of the Joint Center for Structural genomics (**http://www.jcsg.org**; Figure 1) enumerates over 6000 proteins from several model organisms selected for structure determination.

Every target list is necessarily a dynamic data structure, which has to be regularly updated to reflect progress in experimental work and changes in molecular biological databases. Quite often, certain targets get abandoned either because

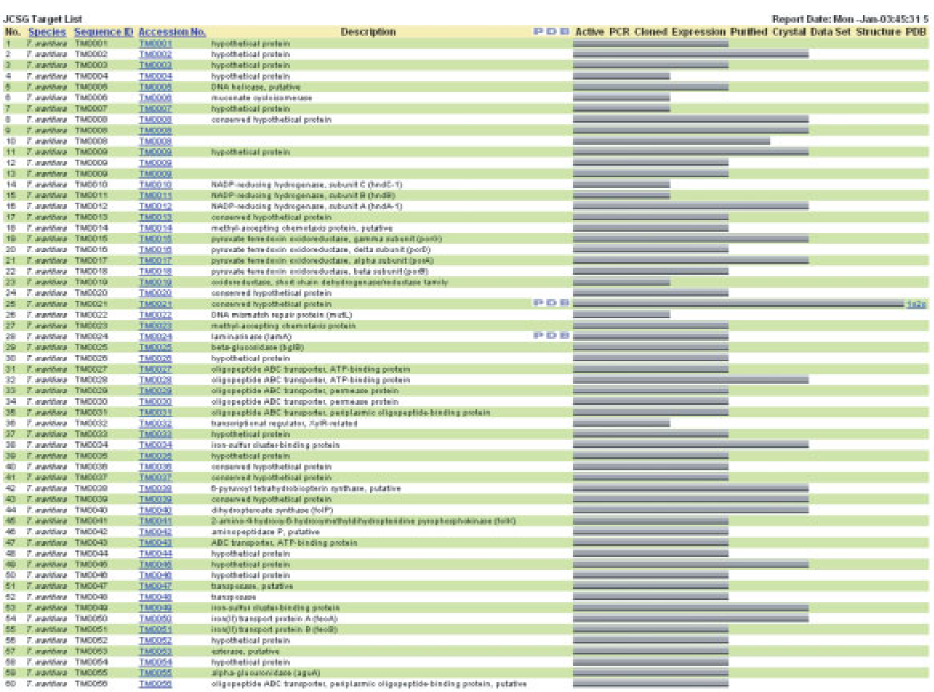

Figure 1 Target database of the Joint Center for Structural genomics (**http://www.jcsg.org**), showing experimental status of each protein selected for structure determination

they prove to be unsolvable or because new information appearing in the public databases invalidates initial rationale for their selection or simply because other research groups also working on this target are more successful. At the same time, new targets may be added to the list on the basis of the latest available evidence.

3. Basic criteria for target selection

Comprehensive functional and structural characterization of gene products by various bioinformatics tools is an important prerequisite for rational target selection. The following criteria are most frequently used as a basis for target selection decisions:

- Is this a soluble or a membrane-bound protein?
  Predicting the location of transmembrane regions and general topology of integral α-helical membrane proteins is possible with reasonable accuracy (Moller *et al*., 2001) and should be supplemented by identification of signal peptides for better results. Prediction of transmembrane β-barrel structures remains difficult because of scarce structural data, but progress is being made (Zhai and Saier, 2002).
- What is known about its function?
  The most commonly used method to predict protein function is based on similarity searches against the entire protein sequence database. Significant similarity to a protein of known function, which may be defined as 40% sequence identity over at least 60% of the protein length, usually serves as a basis for a reasonably confident function prediction, while weak similarity matches allow for only very coarse functional assignments. The presence of conserved sequence motifs as defined by PFAM, SMART, or PROSITE databases (reviewed by Liu and Rost, 2003) usually provides a very strong indication of a protein's membership in a specific functional family. Many additional functional attributes, such as enzyme classes or subcellular localization (e.g., Eisenhaber and Bork, 1998), can be automatically derived using similarity matches to thoroughly annotated proteins of known function. More sophisticated bioinformatics methods based on genomic context explore conservation of gene order, patterns of gene occurrence in different genomes (phylogenetic profiling), or similarity of expression profiles to predict protein function, including its potential interaction partners, in a similarity-free fashion (Galperin and Koonin, 2000).
- What is the taxonomic distribution of this protein?
  Is it found only in one domain of life or in all three? Specifically, are there orthologs from thermophilic species that are usually easier to crystallize? Does it have mammalian orthologs, especially those that are disease relevant? Two particularly interesting classes of targets are gene products encoded in only one organism (so-called genomic orphans (Fischer, 1999)), as well as evolutionary conserved proteins of unknown function. An additional issue is the size of the paralogous family in the genome of interest.
- What is known about its structure?
  Three-dimensional (3D) structures have been determined for less than 0.3% of proteins in completely sequenced genomes (Liu and Rost, 2002). However,

a sizable number of gene products can be linked to proteins whose crystal structure has been determined using similarity searches against the sequences of proteins with known structures. Even greater sensitivity in fold assignment can be achieved with modern threading techniques, such as GENTHREADER (McGuffin and Jones, 2003). These methods attempt to identify sequence-structure fitness using knowledge-based potentials or other statistical parameters derived from the protein structure database. Sequence comparisons with individual structural domains described in the SCOP (Andreeva *et al*., 2004) and CATH (Orengo *et al*., 2001) databases allow predicting putative folding class of the protein and also shed light on its domain structure. Where no similarity to a known structure can be detected, many informative structural features, such as the location of secondary structure elements or the presence of the coiled coil motif, can be delineated directly from protein sequence.

- Does it have structural features that might complicate structure determination?
  Apart from hydrophobic transmembrane segments, further complicating factors are low complexity and disordered regions (Linding *et al*., 2003). Proteins of large size (over 300 amino acids long) are generally not suitable for NMR-spectroscopic analysis.
- Is this protein already being targeted by other groups, and if yes – what is its experimental status?
  Most of the publicly funded structural genomics consortia joined the policy of open dissemination of their target lists and made them available for download in a standard XML-based format. In addition, the Protein Data Bank, which holds all experimentally determined atomic coordinate sets for proteins, provides a central target database for 17 structural genomics projects in the United States, Germany, and Japan (**http://targetdb.pdb.org**). A detailed analysis of the targets currently pursued by these 17 initiatives can be found in O'Toole *et al*. (2003). Similarity comparison of candidate proteins with the latest release of the target database should be routinely performed.

The quality of target-selection decisions critically depends on the general quality of genome annotation. Several software systems have been developed in recent years to automate routine analysis of protein sequences encoded in genomes (e.g., Frishman *et al*., 2001). However, since unsupervised application of automatic bioinformatics methods unavoidably results in a large number of misassignments and wrong predictions, many structural genomics consortia subject automatically produced annotation to careful manual curation.

4. General strategies of target selection

4.1. Organism-based approach

Historically, structural genomics on a single microbial organism was the first to be proposed and implemented, to some extent because of its direct analogy to genome sequencing projects. This proposition is attractive both from the structural

and functional points of view. Exhaustive X-ray or NMR-spectroscopic analysis of all (water-soluble) proteins from a single free-living organism has the potential to provide us with an unbiased view of the protein structure variety sufficient to support cellular life (Frishman and Mewes, 1997). At the same time, structure determination could help to decipher the function of many genomic proteins that are otherwise functionally uncharacterized (Kim, 2000). Efforts to obtain complete structural complements of several prokaryotic species (*Mycobacterium tuberculosis*, *Pseudomonas aerophilum*, *Haemophilus influenzae*, *Methanococcus jannaschii*, *Methanobacterium thermoautotropicum*, *Thermus thermophilis*, and others) are now underway (reviewed in Frishman, 2003). A number of eukaryotic organisms are also being addressed, including *Saccharamyces cerevisiae, C. elegans, D. melanogaster, A. thaliana,* and *H. sapiens.*

What is the current status of functional and structural characterization of a completely sequenced genome and how far are we from completing the structural portrait of a freely living organism? The function of a sizable fraction of gene products remains unknown. For the best studied prokaryotic genome, *Escherichia coli*, the percentage of proteins that still do not have even a coarse functional assignment is impressively low (19.5% according to Serres *et al*., 2004), but for most other genomes it is much higher: 48% for *M. tuberculosis* (Camus *et al*., 2002), 30% for *S. cerevisiae* (**http://mips.gsf.de**), and roughly 40% for *Arabidopsis thaliana* (Klaus Mayer, personal communication). The number of transmembrane proteins is remarkably constant in genomes of varying complexity, between 20 and 30% of the proteome (Frishman and Mewes, 1997). Typically, up to a half of all proteins can be attributed to a known structural domain, as represented in the SCOP database (Frishman *et al*., 2001). Importantly, low complexity and disordered regions are most prominent in higher eukaryotic genomes, where at least short predicted regions of biased composition are detected in nearly every gene product, while in prokaryotic genomes they affect 2–3% of proteins.

Computationally derived statistics of the type discussed above serve as a starting point for devising target-selection strategies for the single-organism approach (Frishman, 2002; Liu and Rost, 2002; Grigoriev and Choi, 2002). The target list must reveal the minimal set of sufficiently long sequence segments that possess yet unknown 3D structures. Given the high abundance of duplication modules, both on the level of whole genes or parts of genes, intrinsic to all complete genomes a crucial step in creating the list of putative structural targets involves grouping together proteins sharing similar sequence segments. This is typically achieved through single-linkage clustering of amino acid sequences based on pairwise similarity comparisons. The problem is that joint mosaic occurrence of multiple conserved protein modules leads to the well-known phenomenon of domain chaining, such that totally unrelated protein sequences may end up in the same cluster. Partitioning such single-linkage clusters into single domain clusters may represent a significant algorithmic challenge (*see* e.g., Enright and Ouzounis, 2000).

The complexity of single-linkage clusters can be reduced by considering predicted structural attributes of protein domains and filtering out those sequence segments that do not pass the minimal criteria for valid targets (Frishman, 2002). For example, out of five sequence-similar proteins from the *M. tuberculosis* genome shown in Figure 2, three will be immediately rejected either because they are

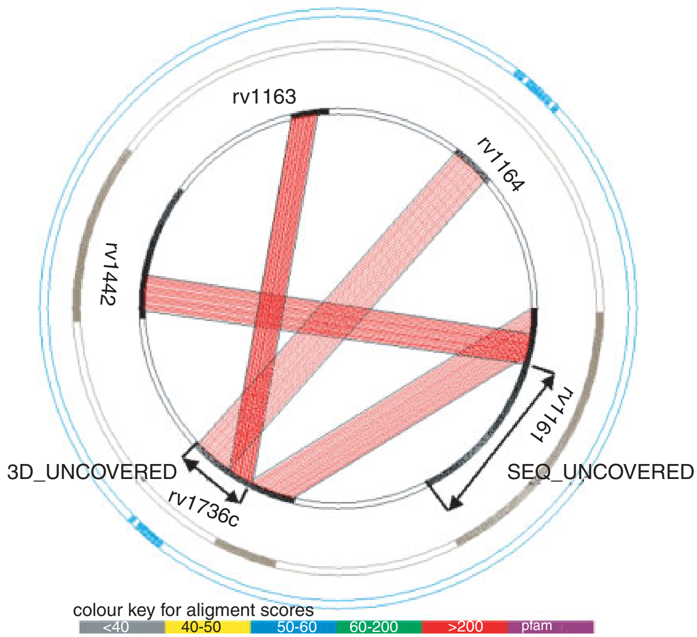

Figure 2 Circular representation of a single-linkage cluster. On the inner circle, five *M. tuberculosis* gene products (rv1164, rv1161, rv1736, rv1442, and rv1163) are shown as black sectors. The N- to C-terminal direction is clockwise. Sequence regions aligned by BLAST after an all-against-all comparison of *M. tuberculosis* proteins are joined by stripes colored according to the BLAST alignment score. On the next (middle) circle shown in brown color similarity hits in the database of protein sequences with known three-dimensional coordinates are mapped. The outer circle, shown in blue, indicates the location of predicted transmembrane regions. Further, parameters used for cluster analysis are the fraction of each protein sequence uncovered by structural information (3D_UNCOVERED) and possessing no similarity to other sequences in the cluster (SEQ_UNCOVERED) (Reproduced from Frishman D (2004) Knowledge-based selection of targets for structural genomics. *Protein Engineering*, **15**, 169–183 by permission of Oxford University Press)

predicted to be membrane-bound or because they show a significant sequence similarity to proteins of a known structure. The remaining allowable targets for structure determination are either the protein *rv1163* or the middle domain of *rv1736c*. Proceeding in this fashion, it is possible to automatically derive a putative target list for any completely sequenced genome that has been appropriately annotated. For example, single-linkage clustering of 4187 proteins encoded in the *M. tuberculosis* proteins results in 380 single-linkage clusters containing 2220 sequences and 1967 singlets – sequences not having any paralogs in the genome (Figure 3). At subsequent steps of the procedure, global redundancy between clustered sequences as well as partial domain overlaps are being resolved using an iterative procedure that involves reclustering of proteins each time a certain member of a single-linkage cluster is excluded.

Such knowledge-based approach based on excision of structurally characterized and transmembrane regions as well as gradual simplification of single-linkage clusters leads to 1544 gene products, or roughly 30% of the proteome, qualifying

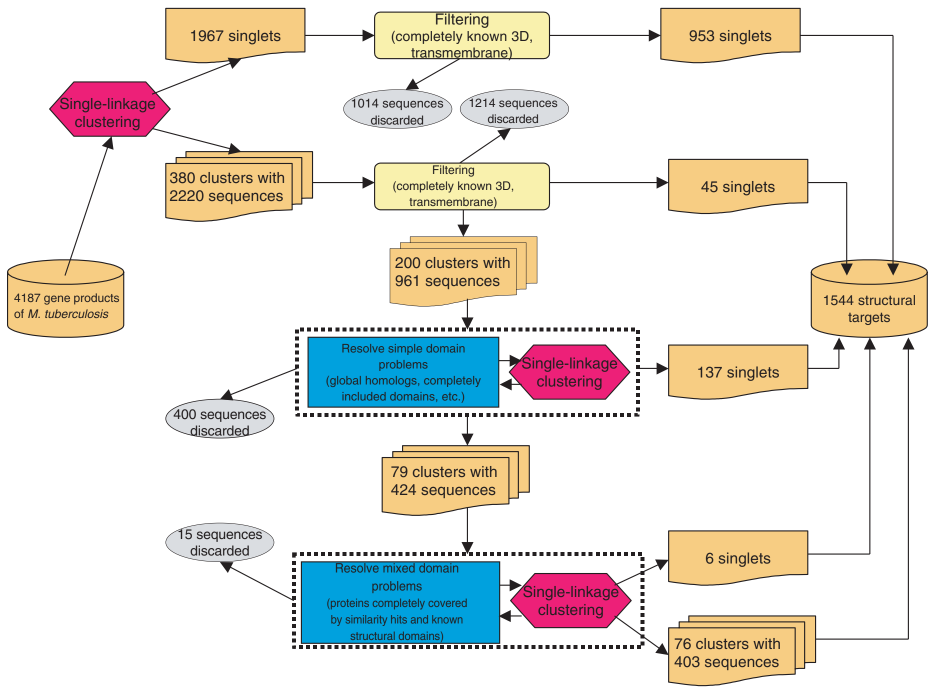

Figure 3 Flowchart of the target-selection algorithm, exemplified using the *E. coli* genome. The entire protein complement of *E. coli*, comprising 4277 gene products, is subjected to single-linkage clustering and gets split into 2235 clustered sequences and 2042 singlets (sequences not having any paralogs in the genome). Both subsets are filtered to exclude transmembrane proteins and those proteins that are completely structurally characterized. The resulting singlets are declared structural targets. The remaining 701 sequences are subjected to two stages of iterative reclustering. At the first stage, simple domain problems, such as cannibalization of a short domain by a longer one are resolved. At the second stage, more complex situations involving proteins with domain similarities to protein of known structure are treated. At each iteration, redundant sequences are excluded from further consideration and clusters reduced to just one sequence become singlets and are added to the target pool. Sequences remaining in the single-linkage clusters after the application of the algorithm are also declared structural targets since they are guaranteed to possess at least one unique and sufficiently long domain not covered by structural information

as targets for structure determination. In general, the number of targets in a completely sequenced prokaryotic genome varies between 30 and 60% and is mainly determined by two factors: size and number of paralogous families, on one hand, and the number of gene products that can be assigned to known structures by similarity, on the other hand. Higher degree of duplication (more and larger paralogous families) and higher percentage of proteins for which structural information is already available both lead to reduction of the target number.

Liu and Rost (2002) arrived at similar conclusions. They reported that approximately 48% of all genomic proteins contain structurally uncharacterized regions that do not possess experimentally intractable structural features (transmembrane and low complexity sequence spans, coiled coil), and are thus of interest for structural genomics. For about 54% of individual amino acid residues in complete genomes, there is no structural information.

In addition to computationally derived features of proteins, many other project-specific functional criteria are applied. For example, the *M. tuberculosis* structural genomics project (Goulding *et al*., 2003) is aiming at identifying novel folds, but also considers as particularly attractive targets essential genes, proteins specific to this organism, proteins related to known antituberculosis drug targets, as well as virulence proteins. Additionally, it is required that structural targets have no mammalian homologs, contain 1% of methionines, and are smaller than 50 kDa.

4.2. The quest for novel folds

Perhaps, the most attractive group of targets is constituted by proteins possessing currently unknown folds. Technically, a novel fold may be defined as one that does not show any significant similarity to any previously structurally characterized domain based on automatic (Holm and Sander, 1998), semiautomatic (Orengo *et al*., 2001), or purely manual (Andreeva *et al*., 2004) structure comparison. While every new structure is undoubtedly useful, those shedding light on not-yet-seen topologies are clearly the most exciting ones. Unfortunately, while the number of atomic coordinate sets deposited with the PDB each year is dramatically increasing, the percentage of novel folds among newly determined structures in recent years is already distressingly low (1–5%, Koppensteiner *et al*., 2000; Orengo *et al*., 2001) and continues to diminish.

If a protein under study displays a significant sequence similarity to a known structure, it can be confidently classified as a known fold. The opposite is not necessarily true: the absence of sequence similarity to a PDB protein does not prove that the fold is novel. 3D structure is evolutionarily more conserved than sequence, and hence proteins belonging to the same fold class may have completely dissimilar primary structures.

There are essentially only two ways to further advance the prediction of novel folds from sequence. The first possibility is to enhance the identification of sequences that *do not* possess a novel fold, thus narrowing down the pool of potential candidates for yet unknown topologies. This may be achieved by developing more sensitive threading techniques (McGuffin and Jones, 2003) and providing careful statistical estimates for novel fold confidence (Mallick *et al*., 2000). The second possibility is to use unconventional techniques not directly based on sequence comparison between a query sequence and a library of folds. For example, the approach developed by Portugaly *et al*. (2002) takes advantage of the exhaustive classification of all protein sequences available in the SWISS-PROT database represented as a directed graph. Clusters of related sequences on this graph roughly correspond to protein families. An assumption is made that the likelihood of producing a new fold is determined by the distance on the graph between the sequence cluster it belongs to and the nearest cluster occupied by a solved structure.

4.3. Covering sequence space with protein structures

The most general target-selection strategy provides for determining enough structures to characterize the entire population of currently known proteins across

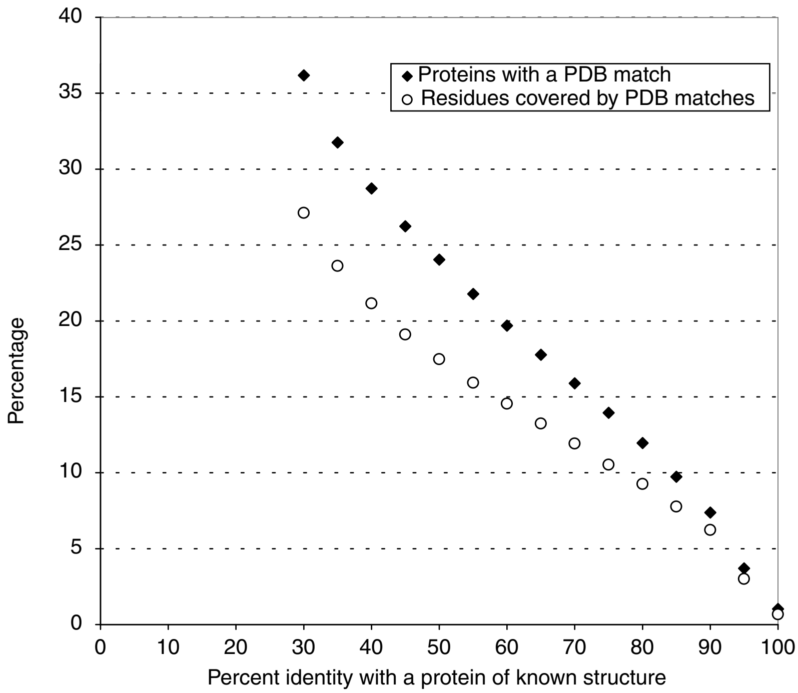

Figure 4 Percentage of proteins and individual amino acid residues in the entire sequence database covered by structural information as a function of minimal allowed sequence identity with proteins of known structure

all organisms. This idea may be viewed as a generalization of the organism-based and fold-centric approaches. The key premise of this strategy is the ability to model structures of a large number of sequences if they display sufficiently high similarity to proteins of known structure (Sanchez *et al*., 2000). The target-template sequence identity, often called *modeling distance*, determines the quality of resulting models. For coarse models, 30% of sequence identity may be sufficient, while for accurate comparative modeling at least 60% are required. As seen in Figure 4, roughly 20% of all proteins known today are amenable to homology modeling at a modeling distance of 60%.

The desired model quality is thus the key factor determining the number of structure determinations needed to cover all protein sequences with structural information. Because of the mosaic multidomain composition of proteins, especially eukaryotic ones, the most appropriate approach is to provide such coverage on the domain basis, rather than for full-length amino acid chains. Computational tests show, for example, that at least 13 000 new structures are necessary to bring each nontransmembrane sequence domain defined in the PFAM database within a modeling distance of 30% from a known PDB structure (Vitkup *et al*., 2001). However, since not all domains are encompassed by the PFAM database, the actual number of new structures required to cover all sequences is much higher. Using recently developed advanced alignment techniques, it is possible to generate

accurate alignments and hence homology models of satisfactory quality even at very low (below 20%) sequence identity level (Heger and Holm, 2003), further reducing the number of structures that need to be experimentally solved to achieve full structural coverage of sequence space.

4.4. Increasing the success rate of structural genomics

In addition to various functional and structural attributes discussed above, an important issue in rational target selection is the feasibility of structure determination for a particular protein of interest. In spite of the recent progress in structure determination technology, the success rate of structural genomics remains quite low. Christendat *et al*. (2000) reported that approximately 20% of targets with molecular weight under 20 kDa survive all stages of sample preparation and produce well-diffracting crystals, while for larger proteins this figure does not exceed 5%.

Many structural genomics projects have a clear technological focus, aiming primarily at building a high-throughput structural proteomics pipeline and investigating its main technical bottlenecks. Thus, the target list of the *M. thermoautotropicum* project, comprising 424 out of 900 nonmembrane proteins without known 3D structures, was created not on the basis of functional or structural priorities, but was rather randomly chosen to represent an unbiased sample of soluble proteins from a single organism (Christendat *et al*., 2000). The *T. maritima* project (Lesley *et al*., 2002) pursues all gene products without a structural homolog, including the difficult ones (e.g., membrane proteins), in an attempt to derive a generalized methodology for expression and refolding.

Most of the structural genomics groups began systematic collection of information on successful and failed experiments at all stages of structure determination. On the basis of retrospective analysis of experimental outcomes, attempts are being made to delineate rules for selecting structural targets that are more likely to yield to crystallographic or NMR analysis. Sequence properties that especially strongly influence experimental success include the degree of evolutionary conservation, content of charged residues, presence or absence of hydrophobic patches, number of interaction partners, and length (Goh *et al*., 2004).

4.5. Target selection in real life

Real-life target selection is rarely based on pure bioinformatics. While computational analysis of genomes and proteins does provide an invaluable information basis for structural genomics, many decisions in selecting targets are being driven by pragmatic considerations – availability of experimental material, equipment, and expertise within a given consortium, amount of funding, competitive pressure – as well as scientific intuition, curiosity, and historical background of individual researchers.

Most of the structural genomics projects (**http://www.nigms.nih.gov/funding/psi/psi_research_centers.html**) pursue mixed strategies in picking structural targets and, in fact, the boundaries between these strategies are only relative. For example,

it has been estimated that the genomes of unicellular organisms encode a substantial fraction of all folds adopted in nature – from 25% for small genomes, such as *Mycoplasma genitalium*, to up to 80% in large bacterial genomes and yeast (Wolf *et al*., 2000). This means that projects aimed at systematic determination of structures from model organisms are bound to make a significant contribution towards closing white spots on the protein fold map in the fold-centric and model-centric approaches.

5. Outlook

The technology to select targets for structure determination and the structure determination technology itself evolve in a coordinated fashion. As the latter improves, structural genomics will increasingly be focusing on very difficult targets that are largely out of reach today. The most obvious example of an upcoming target class of major importance is membrane proteins, which at present constitute less than 1% of all structures in the PDB databank. At least two small-scale pilot projects already pursue this class of proteins: MepNet (**http://www.mepnet.org**) and ProAMP (**http://binfo.bio.wzw.tum.de/proj/proamp**). Another nonstandard class of targets, also strongly underrepresented in PDB, is constituted by disordered proteins. These functionally important molecules, highly unstructured as separate entities, are presumed to acquire well-defined shape upon binding with other proteins. It is obvious that these and other challenging targets necessitate substantially different target-selection logic.

In the future, structural genomics will not just be cataloging the shapes of individual biomolecules, but also providing structural insights into the interacting complexes and entire molecular machines, ultimately leading to system-level understanding of the workings in the living cell. Correspondingly, a new quality of computational support will be required, away from sequence-by-sequence analysis towards exhaustive description of cellular functional modules.

Specialist Review

Protein–ligand docking and structure-based drug design

Peter R. Oledzki, Alasdair T. R. Laurie and Richard M. Jackson
University of Leeds, Leeds, UK

1. Introduction

Drug discovery is a time consuming and expensive process, and increasing its speed and efficiency through the application of computational methods has received considerable attention (Jorgensen, 2004). The first stages of the drug design process are lead discovery and lead optimization. Traditionally, many lead compounds have been discovered serendipitously, by chemically modifying and improving existing drugs (the so-called me-too approach) or by isolating the active ingredients in herbal remedies. However, increasing importance is being placed on the discovery of selective biochemical entities that act on distinct molecular targets, such as receptors, enzymes, and ion channels. In addition, many pharmaceutically relevant macromolecular 3D structures from physical (X-ray crystallography and Nuclear Magnetic Resonance) and computational (comparative/homology modeling) sources have become available. The potential of "structure-based" drug design (SBDD) methods were recognized as early as the 1980s, and interest has since grown considerably as demonstrable progress has been made. The critical factors for successful drug design are the identification and optimization of lead compounds whilst averting unwanted side effects.

Recently, experimental high-throughput screening (HTS) methods, involving screening large chemical libraries against a protein target, have become common in the pharmaceutical industry. However, large scale HTS is expensive and it is beneficial to restrict the size of a chemical library to compounds that are most likely to be successful. Virtual screening (VS) of a chemical library is one way for potentially successful compound identification if the structure of the target is known. The term virtual screening has been used to define *in silico* methods that are used to identify ligands that have activity against a specified protein target or a similar activity to an identified "lead" compound. Screening compounds for similar activity to specified ligands with only information derived from those ligands (i.e., no structural information for the macromolecular target) is termed *ligand-based design* and will not be covered in this review. Here, the term virtual screening is used in regard to applications to macromolecular–ligand docking. Both HTS and

VS are limited by the size of the chemical library they use. *De novo* drug design attempts to overcome this limitation by increasing the exploration of chemical search space; however, a limitation of this method is that ligands produced in this way are not always chemically synthesizable. Both VS and *de novo* drug design require a three-dimensional representation of the protein target and are therefore referred to as *SBDD methods*.

2. Prerequisites for structure-based drug design

There are two prerequisites for SBDD. Firstly, a three-dimensional representation of the protein target must be available. Preferably, this structure should be derived from experimental information such as X-ray crystallography or NMR. However, for the appropriate application of SBDD methods, an understanding of the effects and limitations that structural data imposes on the quality of results must be fully taken into account (Acharya and Lloyd, 2005; Davis *et al*., 2003). Alternatively, homology/comparative modeling can be used to obtain a suitable structure. The role and utility of comparative models in drug design have been reviewed at length (Hillisch *et al*., 2004; Jacobson and Sali, 2004; Wieman *et al*., 2004). A model of a protein structure may be created if there is sequence similarity between the target and another protein for which the experimental structure has already been resolved. Drug design is frequently faced with the problem of discovering a ligand for a protein that has no experimentally determined structure. The most prominent examples of this are the G-protein coupled receptors (GPCRs), with 50% of recently developed drugs being targeted against GPCRs (Klabunde and Hessler, 2002). The advent of structural genomics is ultimately expected to yield enough experimental structures to cover fold space (Brenner and Levitt, 2000). Thus, it should become increasingly possible to generate realistic models for any given protein sequence using comparative modeling techniques (Marti-Renom *et al*., 2000).

The second prerequisite for SBDD is the location of the ligand-binding site. Binding sites can be identified by cocrystallization of a protein with a ligand experimentally. Otherwise, using sequence or structural similarity of the site of interest to a known binding site is a common method for the identification of protein functional sites (Campbell *et al*., 2003). Alternatively, there are many computational methods available for the *de novo* identification and mapping of small-molecule binding sites (Sotriffer and Klebe, 2002), with Q-SiteFinder (Laurie and Jackson, 2005) being a specific example.

3. Protein–ligand docking

The docking problem can be defined as “Given the atomic coordinates of two molecules, predict their “correct” bound association” (Brooijmans and Kuntz, 2003). The docking problem relates to the “lock and key” mechanism first proposed by Fischer over 100 hundred years ago. The theory of molecular recognition was further developed by Koshland to encompass conformational changes during the binding event, which has been termed *induced fit* (Koshland, 2004). The

docking problem involves protein–protein interactions, protein–DNA interactions, and protein/DNA–ligand interactions. However, only protein–ligand docking will be discussed here due to its direct relevance to SBDD. Other applications of molecular docking are beyond the scope of this review.

Docking is traditionally viewed as a two-stage problem, with both stages interrelated. The first component of the docking problem relates to the sampling of conformational space to predict the correct orientation and position of a ligand. For rigid-body docking six degrees of freedom apply, three for rotation and three for translation. The second stage of docking relates to ranking of solutions and the determination of favorable conformations within the protein-binding site. This classification of docking solutions is achieved using scoring functions. Scoring functions are an area of great importance and currently the focus of intense research activity and will be discussed in further detail below.

The field of protein–ligand docking has been the subject of interest for many years, with one of the first docking algorithms DOCK being developed as early as 1982 (Kuntz *et al*., 1982). The first generation of automatic docking algorithms only used rigid-body calculations with no simulation of ligand or protein flexibility. However, the importance of conformational change is now well recognized, and docking methods now incorporate ligand flexibility and in some cases protein flexibility. There are numerous protein–ligand docking algorithms with several recent reviews of the methods (Kitchen *et al*., 2004; Kroemer, 2003; Taylor *et al*., 2002).

4. Docking search procedures incorporating conformational change

Many different approaches have been used to solve the problem of ligand flexibility. Docking algorithms sample ligand conformational space using genetic algorithms (Jones *et al*., 1997), Monte Carlo simulations (Goodsell *et al*., 1993; Venkatachalam *et al*., 2003), tabu list searching (Westhead *et al*., 1997), molecular dynamics (Wang *et al*., 1999), energy minimization methods (McMartin and Bohacek, 1997), stochastic tunneling (Mancera *et al*., 2004), probabilistic sampling (Jackson, 2002), and incremental construction (Rarey *et al*., 1996). The sampling method must cover sufficient conformational space to find the correct position and orientation (binding mode) of a ligand within a protein pocket. Therefore the objective of all search procedures is to sample conformational space sufficiently in a time efficient manner. Each individual method achieves this; however, there is always a trade-off between adequately searching conformational space and computational expense. Search methods implemented in docking can be separated into systematic methods, stochastic simulation methods and various hybrid approaches.

Systematic methods try to explore all the degrees of freedom permitted by a molecule, but are prone to combinatorial explosion. Using a fragment-based approach, ligands can be grown in a stepwise or incremental manner within the active site. Rigid ligand fragments can be docked in the site and then linked

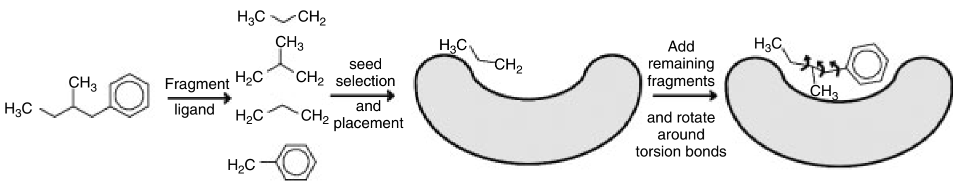

Figure 1 Incremental construction for docking consists of fragmenting a ligand, placing a seed/anchor fragment, and building up the remaining ligand fragments

covalently together; this follows the similar *de novo* ligand-design strategy of place and join (see below). Alternatively the ligand can be separated into core and flexible fragments. The core fragments can be docked into the binding site and used as starting positions for growing the remaining fragments in an energetically favorable manner. This approach has been used in FlexX (Rarey *et al*., 1996), DOCK 4.0 (Ewing *et al*., 2001), and FlexLigDock (Oledzki, Lyon and Jackson, in preparation) (see Figure 1). Other systematic methods consist of pregenerated multiple ligand conformers such as in FLOG (Miller *et al*., 1994) and FRED (1997); these are then docked individually, reducing the search problem to a rigid body docking procedure.

Stochastic search procedures change single ligands or populations of ligands in a random fashion in relation to a predefined probability function. Implementation of a Monte Carlo search (Goodsell and Olson, 1990) and genetic algorithms can be found in the popular docking programs Autodock (Goodsell *et al*., 1996) and GOLD (Jones *et al*., 1997). Other simulation methods, such as using molecular dynamics for sampling conformational space have been less popular for docking. However, many energy minimization techniques have been shown to complement other sampling methods in docking as a refinement step.

The concept of using pharmacophores within SBDD has recently grown in popularity (Dror *et al*., 2004; Guner, 2002; Mason *et al*., 2001). A pharmacophore is defined as "being a set of structural features in a molecule that is recognized at a receptor site and is responsible for that molecule's biological activity" (Gund, 1977). This information can be derived from sets of known active ligands for a target protein. The minimal structural requirements essential for receptor recognition, receptor binding, and biological response, are represented in a pharmacophore. Typically, a pharmacophore consists of three or more feature points such as hydrogen-bonding groups and charged or hydrophobic groups, along with a set of geometrical rules that describe how these features are related in 3D space. A pharmacophore can be used to constrain docking calculations to produce ligand conformations more likely to recreate biologically relevant protein–ligand contacts representing experimentally observed binding modes. Many recent docking algorithms have included pharmacophore constraints to speed up docking calculations and to improve binding mode prediction (Goto *et al*., 2004; Hindle *et al*., 2002; Seifert, 2005; Yang and Shen, 2005).

Structural changes in the receptor upon ligand binding are a common phenomenon (Najmanovich *et al*., 2000). Therefore, the degree to which the protein moves upon ligand binding mirrors the drop in docking accuracy (Erickson *et al*.,

2004). The various effects of protein flexibility on drug discovery have been recently reviewed (Davis *et al*., 2003; Teague, 2003). The issue of addressing protein flexibility is a complex problem, and was initially solved by using soft docking (Jiang and Kim, 1991). Softness allows imprecision in both the protein and ligand structures and models their adaptive changes to each other. Partial side-chain flexibility has also been incorporated into docking procedures (Jones *et al*., 1995; Leach, 1994) among others that have been comprehensively reviewed (Carlson, 2002; Teodoro and Kavraki, 2003). Nevertheless, most of these methods do not include explicit sampling of side chains, such as those implemented in protein–protein docking (Jackson *et al*., 1998) or allow for backbone rearrangements as this would be impracticable for VS of large chemical libraries due to combinatorial explosion. Using multiple receptor conformations (MRCs) (either experimentally or computationally generated) for docking seems to be the most practical approach to date (Teodoro and Kavraki, 2003; Claussen *et al*., 2001). An important advantage of this approach is that the structural space of the binding pocket can be represented in a VS process, even in the case of loop displacements (Cavasotto and Abagyan, 2004). However, the best way to implement protein flexibility in an efficient manner for the VS process is still an unresolved problem (Carlson, 2002).

5. *De novo* drug design tools

De novo drug design involves creating new ligands in a binding site one atom or fragment at a time. This increases exploration of chemical space relative to VS tools, since in the latter there is a predefined compound library. However, a potential disadvantage is that suggested lead compounds may not necessarily be chemically synthesizable. *De novo* drug design tools fall into two main categories, or may use a combination of the techniques: (1) fragment based and (2) atom based. Examples of both types are discussed below.

Fragment-based approaches use molecular fragments to build up molecules. They have an advantage in that molecules have a greater chance of being synthesizable with a realistic structure, but the novelty of the molecules produced is limited by the size of the fragment library. There are two subsets of a fragment-based approach. In the “place and join” method, the molecular fragments are placed independently before attempting to connect them together. The alternative is an incremental construction approach, in which fragments are aligned using the orientation of the growing ligand (Figure 2).

GroupBuild (Rotstein and Murcko, 1993) and LigBuilder (Wang *et al*., 2000) are examples of incremental construction algorithms (Figure 2b). GroupBuild uses a library of 14 organic fragments (formic acid, formaldehyde, formamide, amine, benzene, cyclohexane, cyclopentane, ethane, ethylene, water, methanol, methane, sulfone, and thiophene). A core fragment is docked into the binding site (or a part of a known inhibitor may be used). Fragments are added by replacing hydrogen atoms within the ligand. Fragments are rotated around the vector projection of the replaced bond. Only chemically feasible bonds are allowed. The algorithm uses a greedy strategy, randomly retaining one of the best 25% that scoring presents after

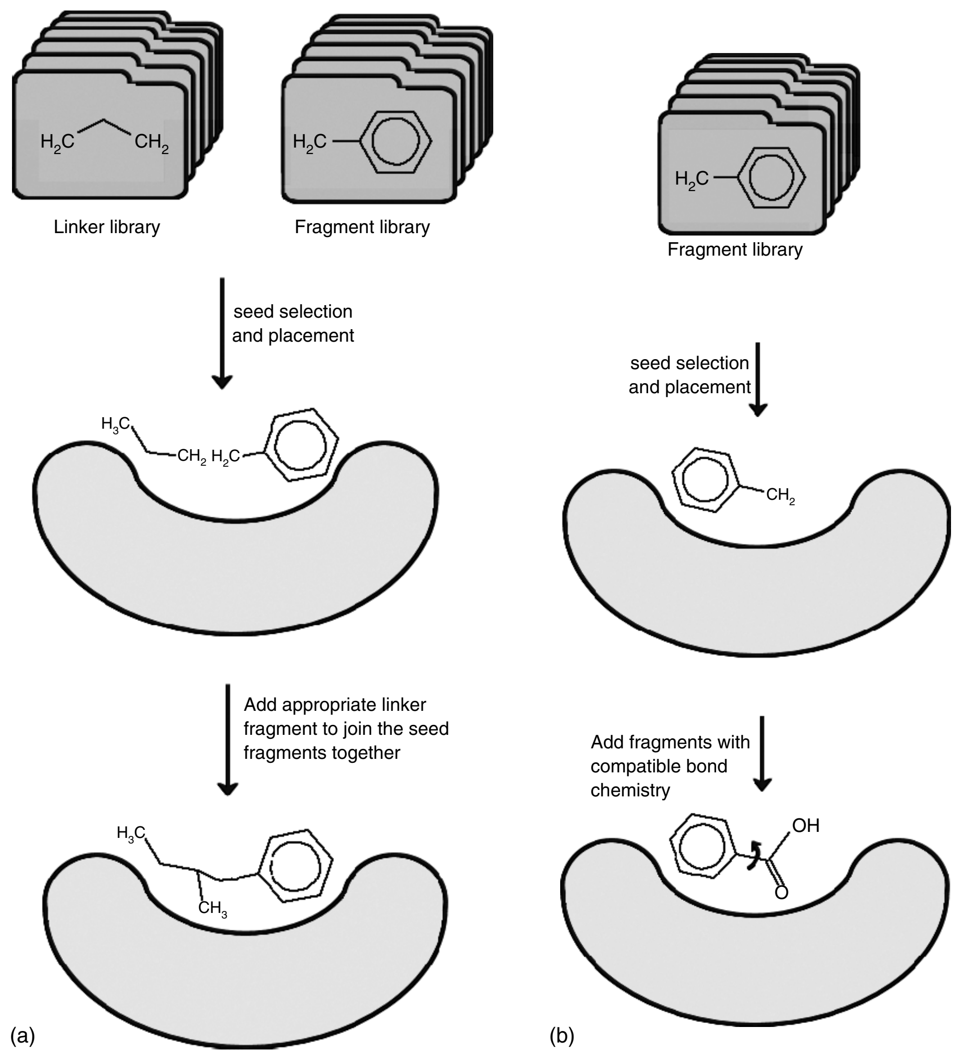

Figure 2 (a) The “place and join” method identifies favorable binding regions for seed fragments or atoms and then attempts to join them together using a suitable linker fragment. (b) The *de novo* incremental construction approach uses a library of fragments, selects an anchor/seed placement and adds fragments from the library with compatible bond chemistry

each round of fragment addition. LigBuilder uses a library of 56 organic fragments. It uses a similar method of incremental construction to GroupBuild. In addition, the program is capable of performing atomic mutations.

SPROUT (Gillet *et al*., 1993) and MCSS/HOOK (Caflisch *et al*., 1993; Eisen *et al*., 1994; Miranker and Karplus, 1991) are examples of “place and join” methods. SPROUT initially identifies target sites in the receptor. A template molecule is then fitted so that it occupies at least one target site. More templates are added such that they (1) interact with the other target sites, (2) do not cause

steric interference with the binding site, and (3) can be joined to the existing templates. Templates are joined together either by fusion or bridge (single bond) formation. SPROUT does not use linker fragments. MCSS/HOOK uses a different "place and join" approach with linker fragments (Figure 2a). MCSS (multiple copy simultaneous search) was developed to determine energetically favorable binding modes of functional groups in a ligand-binding site. Thousands of copies of the functional group of interest are placed in random positions within the binding site. The algorithm uses a Monte Carlo energy minimization. Regions of favorable interactions are indicated by a concentrated localization of functional group copies to regions within the binding site. HOOK uses a database of linker fragments to join together functional groups that are placed in the binding site by MCSS. It fuses bonds within the linker fragment (called *hooks*) with free CH_3–R bonds of the functional groups. HOOK scores the chemical complementarity and steric fit of the resulting molecules within the binding site.

De novo ligands generated by atom-by-atom methods are not limited by the size of a fragment library, but may be less likely to produce realistic or synthesizable ligands. LEGEND (Nishibata and Itai, 1993) forms molecules atom by atom. The first atom is placed at a set distance from a hydrogen bond acceptor in the binding site. New atoms are added, testing all possible dihedral angles and are assigned an atom type and hybridization state. If the atom occupies a forbidden position on the grid, it is rejected. The algorithm terminates at a user defined molecule size. SEEDS (Honma *et al*., 2001), uses LEGEND output to search for commercially available compounds with structural similarity.

Some *de novo* drug design methods do not fall into these three classes. For example, Monte Carlo *De Novo* Ligand Generator (MCDNLG) (Gehlhaar *et al*., 1995), does not use a fragment library, database searching or atom-by-atom approach. The binding cavity is filled with an array of atoms of random type and hybridization. In each Monte Carlo step, parameters such as atom types and bond angles are allowed to change. The process is guided by intramolecular and protein–ligand energy functions as well as penalties on unreasonable chemical structures (such as sp^3-hybridized atoms with double bonds). It produces novel leads, but they are not necessarily chemically accessible.

Testing *de novo* design algorithms is often difficult, as novel molecules must be chemically synthesized and screened against the target to verify that they genuinely interact. Many *de novo* design algorithms are not tested experimentally, unless they are used commercially, which slows their acceptance by the pharmaceutical industry. SPROUT has yielded a number of new leads that have been tested *in vivo* (Han *et al*., 2000; Milne *et al*., 1996), which proves the usefulness of the *de novo* approach to lead generation.

6. Scoring functions

Energy functions are used to estimate binding energies of ligand conformations. "The binding free energy of a protein–ligand complex can be intuitively understood as the difference in how much the ligand likes to be in the protein binding pocket and how much it likes to be in the solvent at infinite separation from the protein"

(Muegge and Rarey, 2001). For ease of calculation the binding free energy has been separated into various terms. Thus the free energy (equation 1) can be expressed as the sum of different parts, sometimes referred to as a *master equation* (Ajay and Murcko, 1995). However, the theoretical justification for this has been challenged, as binding energies are a global property of a system and cannot be expressed as a sum of components (Mark and van Gunsteren, 1994). The free energy can be divided into components that account for the difference in solvation energies of the ligand, protein, and complex (ΔG^{lig}_{solv}, ΔG^{prot}_{solv}, $\Delta G^{complex}_{solv}$), the interaction between the protein and the ligand in complex (ΔG_{int}), entropy changes for the ligand and protein ($T\Delta S$), and conformational changes (reorganization energy) in the ligand and protein ($\Delta\lambda$). This last term involves the loss of internal rotations, and translational/rotational degrees of freedom and change in vibrational free energy upon complex formation. The binding free energy is given by

$$\Delta G_{binding} = \Delta G^{complex}_{solv} - \Delta G^{lig}_{solv} - \Delta G^{prot}_{solv} + \Delta G_{\text{int}} - T\Delta S + \Delta\lambda \qquad (1)$$

The terms in equation (1) (Muegge and Rarey, 2001) have been expressed elsewhere in slightly different forms (e.g. Ajay and Murcko, 1995; Gohlke and Klebe, 2002). They represent binding by partitioning through the use of various empirical factor models. They are known as *partitioning models* because the components are often calculated independently.
